The most prevalent CWA proteins are the microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). They have been described in great detail in *S. aureus* but are also present in *S. epidermidis*, other *Staphylococcus* spp., *Streptococcus* spp. and *Enterococcus* spp. (Foster, 2019). However, the precise number of CWA proteins expressed varies from strain to strain and within a species, and is dependent on growth conditions and growth phase (exponential vs. stationary phase; Foster, 2019). Due to the limited number of proteins expressed on the surface of the bacteria, a single MSCRAMM can carry out several functions. However, all promote bacterial adhesion to abiotic surfaces and synthetic surfaces coated with host extracellular matrix components (such as fibrinogen, fibronectin collagen and laminin), and various host cells (Table 4; Pietrocola et al., 2018; Foster, 2019). A typical MSCRAMM contains a secretory Sec-dependent signal sequence at the N-terminus, and a sorting signal comprising of an LPXTG (Leu-Pro-X-Thr-Gly; X denoted any amino acid) sortase cleavage motif, a hydrophobic domain and positively charged residues at the C-terminus (Fig. 9; Nobbs et al., 2009; Foster, 2019). The proteins are bound to the cell wall peptidoglycan via the C-terminus through the activity of Sortase A, while the N-terminal A domains are projected away from the cell wall surface ready to bind to a suitable host ligand.

CWA proteins and MSCRAMMs have been well studied in *S. aureus*. Depending on strain, *S. aureus* can express up to 24 different CWA proteins, that have multiple roles in promoting adhesion to host cells and tissue, survival in blood during an invasive infection, and in the formation of abscesses in the skin and internally (Table 4; Foster et al., 2014; Foster, 2019). Most *S. aureus* strains have two fibronectin binding proteins (FnBPA and FnBPB), up to five proteins that bind fibrinogen, and several that promote adhesion to squamous epithelial cells and complement factors of the host immune system (Table 4; Foster, 2019). While Group A streptococci such as *Strep. pyogenes* have a MSCRAMM called M protein on their cell surface (Fig. 9; Table 4). They function like a capsule but are a CWA as they have an LPXTG motif and bind both fibrinogen and fibrin, thus inhibiting the alternative complement pathway. M protein is also responsible for inhibiting neutrophil phagocytosis by altering the bacteria's cell surface. The importance of CWA proteins and MSCRAMMs in the pathogenesis of Gram-positive cocci are described in detail in the following reviews (Nobbs et al., 2009; Foster et al., 2014; Pietrocola et al., 2018; Foster, 2019).

Type III secretion system

Type III secretion systems also known as injectosomes are an important virulence factor as they have a molecular syringe-like structure that injects proteins, known as effector proteins directly into eukaryotic cells (Bower and Rosenthal, 2006). Therefore, they are not a true secretion system as they do not export bacterial products into the surrounding environment, but are an effective system that delivers specific virulence factors such as toxins directly into the cytoplasm of the host cell (Fig. 10; Wilson et al., 2002). A type III secretion system consists of a multi-protein ring that attaches it to the cytoplasmic membrane, an inner

Table 4 CWA proteins identified in various Gram-positive bacteria, collated from (Nobbs et al., 2009; Foster et al., 2014; Pietrocola et al., 2018; Foster, 2019; Shivshankar et al., 2009; and Suits and Boraston, 2013).

CWA protein/ MSCRAMM	Bacteria	Ligand	Role in pathogenesis
ClfA	<i>S. aureus</i>	Fibrinogen	Adhesion to fibrinogen, thrombus—endocarditis, medical device infections
ClfB	<i>S. aureus</i>	Complement factor I Fibrinogen	Inhibition of opsonophagocytosis—bacteremia, sepsis Adhesion to fibrinogen, thrombus—endocarditis, medical device infections Adhesion to desquamated epithelial cells—nasal colonization Enhanced survival from neutrophils—bacteremia
FnBPA	<i>S. aureus</i>	Fibronectin	Adhesion to fibronectin, thrombus—endocarditis, medical device infections Biofilm formation—medical device infections Invasion adjacent endothelium and epithelial cells in mammary glands—mastitis Abscess development
FnBPB	<i>S. aureus</i>	Fibronectin	Adhesion to fibronectin—medical device infections Biofilm formation—medical device infections Invasion epithelial cells in mammary glands—mastitis Abscess development
Cna	<i>S. aureus</i>	Collagen Complement protein C1q	Adhesion to collagen-rich tissue e.g., cartilage within joint and blood—septic arthritis Prevention of complement activation, and enhanced survival in
SdrE	<i>S. aureus</i>	Complement factor H	Immune evasions, inhibition of complement in degradation of C3b
SdrD	<i>S. aureus</i>	Desquamated epithelial cells	Nasal colonization?
Protein A	<i>S. aureus</i>	IgG von Willebrand factor	Inhibition of opsonophagocytosis Increased inflammation Endovascular infection, endocarditis
SasG	<i>S. aureus</i>	Fibronectin	Biofilm formation—medical device infections Adhesion to desquamated epithelial cells
Embp	<i>Staphylococcus epidermidis</i>	Fibronectin	Adhesion to fibronectin, promotes accumulation Adhesion to conditioned biomaterial?
SdrG/Fbe	<i>S. epidermidis</i>	Fibrinogen	Adhesion to fibronectin Promotes adhesion to conditioned biomaterial—medical device infections
SdrF/Geh	<i>S. epidermidis</i>	Collagen	Adhesion to collagen deposited on ex vivo biomaterial—medical device infections
SdrI	<i>Staphylococcus saprophyticus</i>	Fibronectin Collagen	Adhesion to fibronectin and collagen—persistence in urinary tract infection
Fbl	<i>Staphylococcus lugdunensis</i>	Fibrinogen	Adhesion to fibrinogen—medical device infections?
SpsD	<i>Staphylococcus pseudintermedius</i>	Fibrinogen Fibronectin Cytokeratin 10	Adhesion to canine fibrinogen, fibronectin and cytokeratin 10—colonization of the host and skin infection
SpsL	<i>S. pseudintermedius</i>	Fibrinogen Fibronectin	Adhesion to canine fibrinogen and fibronectin—colonization of the host and skin infection
M protein	<i>Strep. pyogenes</i>	Fibrinogen Fibronectin Plasminogen Complement factor H	Adhesion to fibrinogen—pro-inflammation, anti-phagocytic activities, Adhesion to epithelial cells Adhesion to plasminogen—increase bacterial extracellular proteolytic activity. Inhibits complement activation
FbaA	<i>Strep. pyogenes</i>	Fibronectin Complement factor H	Adhesion to fibronectin
SfbI	<i>Strep. pyogenes</i>	Fibronectin	Adhesion to fibronectin
ScIA, ScIB	<i>Strep. pyogenes</i>	Collagen	Adhesion to collagen

SrpA	<i>Strep. pyogenes</i>	Multiple substrates	Adhesion to platelets
Mrp	<i>Strep. pyogenes</i>	Fibrinogen	Adhesion to fibrinogen
Lbp,	<i>Strep. pyogenes</i>	Laminin	Adhesion to laminin and epithelial cells
Protein H	<i>Strep. pyogenes</i>	IgG	Escape detection by immune system
SfbI/PrtF1	<i>Strep. pyogenes</i>	Fibronectin	Adhesion to fibronectin—adhesion epithelial/endothelial cells
		IgG	Escape detection by immune system
SibA	<i>Strep. pyogenes</i>	IgG, IgA, IgM	Escape detection by immune system
Srr1/Srr2	<i>Strep. agalactiae</i>	Fibrinogen	Adhesion to fibronectin, epithelial cells, platelets, and salivary glycopeptides
		Cytokeratin	Role in thrombus formation?
FbsA, FbsC	<i>Strep. agalactiae</i>	Fibrinogen	Adhesion to fibronectin—adhesion epithelial/endothelial cells
PbsP	<i>Strep. agalactiae</i>	Plasminogen	Adhesion to plasminogen
			Role in transmigration across brain endothelial cells
PfbA	<i>Strep. pneumoniae</i>	Fibronectin	Adhesion to and evasion of epithelial cells
		Plasminogen	
PsrP	<i>Strep. pneumoniae</i>	Keratin 10	Adhesion to lung epithelial cells

Fig. 9 Structural motifs of some CWA proteins in *S. aureus* (Clf, Sdr, FnBPs, Cna, SasG and Ebh), *S. epidermidis* (Sdr, Aap and Embp), and *Strep. pyogenes* (Srr, Sfbl, SclA, and M protein). Each CWA protein contains a secretory signal sequence (S) at the N-terminus, and a proline-rich wall-spanning region (W), LPXTG motif, and sorting signal (SS) at the C-terminus that promote covalent anchorage to the cell wall PG. A, ligand binding domains; R, serine-aspartate dipeptide repeats (Clf, Sdr, Srr) or fibronectin-binding repeats (FnBP/Sfbl); B, variable repeat domain with ligand-binding properties; C, albumin-binding domain; G5E repeat region promote adhesion and biofilm formation when the A domain is removed; FIVAR, found in various architecture repeats and FIVAR-GA, FIVAR-G-related albumin binding are two long repeat regions with fibronectin binding properties; DUF, domains of unknown function. Surface proteins of *Staphylococcus epidermidis*. *Frontiers in Microbiology* **11**: 1829.

tube that traverses the bacterial peptidoglycan and outer membrane layers, and a needle-like tip that pierces through the eukaryotic cell membrane by forming a pore, delivering the effector proteins directly into the host cell cytosol (Fig. 10; Bower and Rosenthal, 2006). Type III secretion systems have been found in Gram-negative bacteria such as enteropathogenic *E. coli* (EPEC, diarrhoea), *P. aeruginosa*, *Shigella flexneri* (shigellosis, diarrhoea), *Salmonella typhimurium* (typhoid), *Yersinia* spp., and *Chlamydia trachomatis* (chlamydia). Of those identified, they have been found to mediate the bacteria adhesion and invasion to host cells, interfere with host cell signaling, induce cytoskeletal rearrangements, promote host cell apoptosis, and up- or down-regulate cytokine production (Wilson et al., 2002; Bower and Rosenthal, 2006). The actual effector proteins and their virulence properties vary among the different bacteria but without a type III secretion system the bacteria are less virulent (Wilson et al., 2002).

Lipopolysaccharide (LPS)

Lipopolysaccharides (LPS) as mentioned earlier are specific to Gram-negative bacteria and are part of their outer membrane. The lipid A portion is the endotoxin and is a potent pathogen-associated molecular pattern (PAMP) toxin, and as it is cell bound is only released or shed from the outer membrane when the bacterial cell lyses. In pathogenic bacteria that cause food poisoning like *E. coli* and *Salmonella*, the shed LPS binds to the phagocyte pattern recognizing receptors (PRR) on phagocytes, activate B cells and stimulate expression of pro-inflammatory cytokines that induce fever, diarrhoea and the life threatening condition, sepsis/septic shock (Murray et al., 2015; Wooldridge, 2018). *N. meningitidis* (meningitis) also shed a related

Fig. 10 Schematic of a type III secretion system. Adapted from Hotinger JA and May AE (2020) Antibodies inhibiting the type III secretion system of Gram-negative pathogenic bacteria. *Antibodies* 9: 35.

molecule, lipooligosaccharide that also stimulates an innate immune response due to its lipid A portion (Bower and Rosenthal, 2006). Further details on the host immune response to LPS exposure can be found in Chapter 49 (Immunity to bacterial infections).

Summary

Bacteria are small unicellular prokaryotic cells with one common feature is their cell wall structure and organization, that can be split into three parts, the cytoplasm, cell envelope and external cell surface structures. The cytoplasm is the inner most part of the bacterial cell, within which is the nucleoid that contains a single chromosome/DNA stand, ribosomes, inclusion bodies, and in some bacteria, plasmids. The cell envelope is composed of the cytoplasmic membrane, a semipermeable phospholipid bilayer that regulates movement of substances in and out of the cell; and the cell wall which covers the whole cell giving it its strength and shape while protecting it from the external environment. Differences in the cell wall PG composition are used to differentiate between Gram-positive and Gram-negative bacteria. The external cell surface structures are associated with virulence. These include capsule/capsular polysaccharide and slimes that help with surface adhesion and protection from phagocytosis; flagella for motility; fimbriae for adherence; and pili for adhesion, twitching motility, and DNA transfer. Finally, many clinically relevant bacteria have additional virulence factors on their cell wall surface, such as CWA proteins in Gram-positive bacteria, which are important for adhesion, and eukaryotic host cell colonization and evasion; and in Gram-negative bacteria, Type III secretion systems used to inject toxic proteins directly into eukaryotic host cells, and LPS an endotoxin and powerful inflammatory stimulant. Thus, these small microorganisms are well adapted and continually evolve to survive in various environments.

Glossary

Anabolism The process by which living organisms synthesize complex molecules from simpler ones, coupled with energy storage.

Autotrophs Organisms which use carbon dioxide as their sole source of carbon for organic matter synthesis, also known as "primary producers".

Catabolism The process by which living organisms break down complex molecules into simpler ones, coupled with energy release.

Chemolithotrophs Organisms which utilize inorganic compounds found in the environment as their main energy source.

Chemoorganotrophs Heterotrophic organisms which utilize organic compounds found in the environment as their major carbon and energy-yielding substrates.

Endergonic A reaction that absorbs free energy. The net change in free energy at the end of the reaction is positive.

Exergonic A reaction that releases free energy. The net change in free energy at the end of the reaction is negative.

Fermentation Enzyme-catalyzed breakdown of energy-rich compounds by microbes under anoxic conditions.

Heterotrophs Organisms which source their carbon from organic compounds which they oxidize to yield energy and generate the building blocks for biosynthetic processes.

Oxidative phosphorylation The use of substrate oxidation to drive an [electron transfer chain](#), coupled to energy conservation via an electrochemical transmembrane gradient under aerobic conditions.

Phototrophs Organisms which contain colored pigments which allow the conversion of solar energy to chemical energy through photosynthesis.

Redox Reactions involving simultaneous reduction and oxidation of chemical species.

Nomenclature

G Gibbs free energy

ΔG° The change in free energy during a chemical reaction under standard conditions (pH 7, 25 °C, 1 atm and 1 M concentration), expressed in kilojoules (kJ)

E_0' Reduction (or redox) potential expressed in Volts (V) under standard conditions

Introduction

Metabolism encompasses all chemical reactions which occur within a living organism. Its main purposes are, (1) to convert nutrients into a usable form of energy to sustain key cellular processes, (2) acquire the building blocks for cellular growth and (3) eliminate waste products. In the context of infection and immunity, host-microbe interactions are governed by the dynamic relationship which exists between the metabolic pathways of these players. The outcome of these metabolic interactions may be beneficial or destructive to the host. Commensal microbes, for example, can break down indigestible carbohydrates which are consumed by the host, releasing nutrients which are essential for human health (Gibson and Roberfroid, 1995; Gibson et al., 2004). They also suppress the growth of pathogens through nutrient depletion (Abt and Pamer, 2014). When the metabolic balance is tipped in favor of pathogens, this may lead to serious consequences to the host (Carding et al., 2015). Understanding the metabolic pathways employed by our resident microbial population is therefore key in developing new strategies to boost the immune system and suppress pathogen growth, thereby promoting human health.

In order to understand how and why metabolic reactions arise, it is important to consider the Laws of Thermodynamics. The First and Second Laws of Thermodynamics were defined by Rudolf Clausius and William Thomson (Kelvin) ca. 1850. These laws are unifying principles in biology and govern all chemical reactions in living organisms. The First Law of Thermodynamics states that all the energy within a closed system, e.g., the Universe, is constant. Energy may transform from one form to another, but it cannot be created or destroyed. The Second Law of Thermodynamics states that each of these energy transformations increase the disorder, or entropy, within a system. This means that no energy transfer is completely efficient due to some energy being lost in an unusable form (e.g., via heat or waste products). The more energy that is lost from a system the more disordered that system becomes. Microbes have evolved ingenious ways to mitigate this tendency towards entropy, via for example, DNA repair, antioxidant defense and sporulation or encystation in response to hostile environments. Many are also able to switch their mechanisms of energy conservation in response to nutrient availability in the environment (Passalacqua et al., 2016). All such processes are energetically demanding, therefore living organisms are engaged in a constant battle to maintain their highly ordered, low entropy state, otherwise known as homeostasis.

This chapter covers the various biochemical mechanisms utilized by microorganisms to conserve and consume energy. It begins by reviewing the basic building blocks and mechanics of energy conservation ("Bioenergetics and redox reactions" and "Energy sources" sections) followed by an overview of the main pathways for energy generation utilized by microorganisms under a range of environmental constraints ("Catabolic pathways" section). The chapter concludes with a short description of key energy-consuming biosynthetic pathways which facilitate cellular growth and survival ("Anabolic pathways: Biosynthesis" section).

Bioenergetics and redox reactions

The definition of energy is the ability to do work. Energy can be quantified in units of kilojoules (kJ), which is a measure of heat energy. The remaining energy following a chemical reaction which is not released as heat and still available to do work is known as Gibbs free energy (G). The change in free energy during a chemical reaction under standard conditions (pH 7, 25 °C, 1 atm and 1 M concentration) is abbreviated as ΔG^0 . If ΔG^0 is negative the reaction is exergonic or energy-yielding. If ΔG^0 is positive the reaction is endergonic, or energy-requiring.

Oxidation-reduction or redox reactions play a key role in cellular energy conservation. Oxidation and reduction involve the removal or addition of electrons (e^-) to a substance, respectively. In biochemistry, the transfer of an electron is often accompanied by the transfer of a proton (H^+). Redox reactions require an electron donor, from which electrons are removed and transferred to an electron acceptor. During this process, the electron donor becomes oxidized and the electron acceptor becomes reduced. For example, water (H_2O) is formed from a redox reaction between hydrogen (H_2 , the electron donor) and $\frac{1}{2}$ oxygen (O_2 , the electron acceptor), as per Eqs. (1)–(4).

Reduction potentials

The tendency of a compound to become oxidized or reduced depends on the reduction (or redox) potential, expressed as E_0' under standard conditions (pH 7), of their half reaction. Most molecules can either behave as electron donors or acceptors, depending on the substances with which they react. For example, when water is formed (see Eqs. 1–4), the constituents on each side of the arrow represent a redox couple, e.g., $2H^+/H_2$ or $\frac{1}{2} O_2/H_2O$. E_0' refers to the reduced constituent of a redox couple (by convention is always written on the right). A negative E_0' value indicates that the reduced constituent of a redox couple has a greater tendency to donate electrons than does the oxidized constituent to accept them. This is the case for the $2H^+/H_2$ couple where E_0' is -0.42 V. A positive

Fig. 1 A summary of the key redox couples involved in anaerobic and aerobic respirations within different microorganisms. The reduction potentials (E'_0) are ordered from the most electronegative to the most electropositive under anoxic to oxic habitats. Madigan MT and Martinko JM (2006). *Brock Biology of Microorganisms*, 11th edn., pp. 558. Upper Saddle River, NJ: Pearson Education, Inc., Fig. 17.35.

E'_0 value indicates that the reduced constituent has a lower tendency to donate electrons, whilst the oxidized constituent has a greater tendency to accept them. This is the case for the $\frac{1}{2} \text{O}_2/\text{H}_2\text{O}$ couple where E'_0 is +0.82 V. The greater the difference in E'_0 between the electron donor and acceptor in a reaction, the greater the energy that is released. $\Delta E'_0$ is therefore proportional to ΔG^0 . A summary of the key redox couples utilized in the metabolic pathways of different microorganisms is presented in Fig. 1, along with their reduction potential values (Madigan and Martinko, 2006).

Electron carriers

Electron transfer in redox reactions usually rely on the presence of electron carriers. There are two main classes of electron carriers: (1) coenzymes, which are freely diffusible, and (2) prosthetic groups, which are tightly bound to the enzymes involved in redox reactions. Nicotinamide-adenine dinucleotide (phosphate), in its oxidized, NAD(P)^+ , or reduced, NAD(P)H , form is an example of a diffusible coenzyme which acts as an intermediary for reactions between chemically dissimilar molecules. $\text{NADP}^+/\text{NADPH}$ is typically used in anabolic reactions whereas NAD^+/NADH is used in catabolic reactions. The $\text{NAD(P)}^+/\text{NAD(P)H}$ redox couple has a $\Delta E'_0$ value of -0.42 V, making NAD(P)H an efficient electron donor. NADH dehydrogenases contain a prosthetic group which can reduce or oxidize NAD^+ (by accepting 2H or $2\text{e}^- + 2\text{H}^+$) and $\text{NADH} + \text{H}^+$ (by donating $2\text{e}^- + 2\text{H}^+$), respectively. Flavin mononucleotide (FMN) and flavin-adenine dinucleotide (FAD) are examples of flavin prosthetic groups, bound to flavoproteins. Flavins can accept 2e^- and 2H^+ but can only donate electrons. Cytochromes have prosthetic groups containing a porphyrin ring (heme), which undergo redox reactions involving a single electron at the iron-containing active site. Non-heme iron-sulfur proteins, e.g., ferredoxin, are another important prosthetic group, which like cytochromes can only carry electrons. Finally, hydrophobic molecules called quinones are also involved in electron transport and can accept 2e^- and 2H^+ but can only donate electrons.

Energy conservation

The energy released during redox reactions needs to be conserved by the cell in order to fuel energy-demanding processes. As energy conservation in itself is an energy-requiring process, cells tend to rely on compounds with a ΔG^0 of $>30 \text{ kJ mol}^{-1}$ as "energy currencies." The main energy currency produced through catabolic reactions is the molecule adenosine triphosphate (ATP). This is an energy-rich molecule which is universal across the domains of life. ATP stores potential energy in the form of two high energy phosphoanhydride bonds. When hydrolyzed in endergonic reactions, each of these bonds release 32 kJ mol^{-1} of energy under standard conditions. Derivatives of coenzyme A are also used to conserve the energy released during exergonic reactions. These derivatives, e.g., acetyl-CoA ($\Delta G^0 = -31 \text{ kJ mol}^{-1}$), contain high-energy thioester bonds. The energy released when these bonds are hydrolyzed is conserved in the production of ATP. As demand for ATP is high within an actively growing cell, adenosine monophosphate (AMP) - adenosine diphosphate (ADP)—ATP cycling is a dynamic process. For long-term storage, cells must conserve energy in the form of insoluble polymers. In the absence of an external substrate, these can be oxidized to release ATP as maintenance energy in order to maintain cellular growth. Polyglucose such as glycogen and starch, and lipid-based polymers such as poly- β -hydroxybutyrate, are examples of polymers used by microorganisms as long-term energy reserves.

Energy sources

All life on Earth is carbon-based. This makes carbon a basic requirement as a metabolic substrate. The ubiquity of carbon as a nutrient is due to its ability to form four simultaneous bonds with other atoms. This important feature facilitates the assimilation of long molecular chains, forming the basis of DNA, proteins and sugars. Heterotrophic organisms source their carbon from organic compounds which they oxidize to yield energy and generate the building blocks for biosynthetic processes. Autotrophs on the other hand use carbon dioxide (CO_2) as their sole source of carbon for organic matter synthesis. These are also known as “primary producers” as all organic material on Earth is synthesized by such organisms.

Over 4 billion years of evolution, microbes have developed innumerable metabolic strategies for energy conservation, allowing them to flourish in almost every environment on Earth. All microbes fall into one of three broad metabolic classifications, according to their choice of energy-yielding substrate. (1) Chemoorganotrophs are heterotrophic organisms which utilize organic compounds found in the environment as their major carbon and energy-yielding substrates. (2) Chemolithotrophs utilize inorganic compounds found in the environment as their main energy source. For example, the sulfur-oxidizing lithotrophs convert hydrogen sulfide (H_2S) to elemental sulfur (S_0) and S_0 to sulfate (SO_4). So far, chemolithotrophy has only been identified in prokaryotes. This lifestyle means that the organism does not need to compete with chemoorganotrophs for organic substrates, as they can exploit the substrates that are inaccessible to most, and furthermore can live alongside such organisms by feeding on their waste products (e.g., H_2 and H_2S). Many chemolithotrophic organisms are autotrophs (also known as lithoautotrophs or chemoautotrophs), sourcing their carbon from CO_2 . (3) Phototrophs contain colored pigments which allow the conversion of solar energy to chemical energy through photosynthesis. Most phototrophs are autotrophs. Although of great ecological significance, phototrophic microorganisms do not play a significant role in human infection and immunity therefore will not be discussed further in the context of this chapter.

Catabolic pathways

Fermentation

Fermentation involves the extraction of energy from carbohydrates under anoxic conditions. Glycolysis, or the Embden-Meyerhof pathway, is one of the most common fermentative pathways (see Fig. 2). In this pathway, the exogenous electron donor, most commonly glucose, is oxidized to pyruvate (and H^+) via three main enzymatic stages. Stage I involves a series of preliminary reactions which requires the expenditure of two molecules of ATP. The first is used by the enzyme hexokinase to phosphorylate glucose to glucose-6-phosphate. Isomerase then converts glucose-6-phosphate into an isomeric form, fructose-6-phosphate. This is then further phosphorylated by phosphofructokinase to yield fructose-1,6-bisphosphate at the expense of another molecule of ATP. The final step of Stage I involves aldolase, which splits fructose-1,6-phosphate into two units of the 3-carbon molecule, glyceraldehyde-3-phosphate.

Stage II marks the first of a series of redox reactions involved in glycolysis with the conversion of glyceraldehyde-3-phosphate to 1,3-bisphosphoglyceric acid via glyceraldehyde-3-phosphate dehydrogenase. This enzyme contains the coenzyme NAD^+ , which forms NADH (used later in Stage III) by accepting 2e^- and 2H^+ from the phosphorylation of glyceraldehyde-3-phosphate. Note that this reaction, and all subsequent reactions occur twice simultaneously due to the presence of two molecules of glyceraldehyde-3-phosphate from Stage I. In total, four molecules of ATP are synthesized during Stage II, due to the conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate, via the action of phosphoglycerokinase and later, the conversion of phosphoenolpyruvate to pyruvate, via pyruvate kinase. A number of steps precedes the latter, notably the conversion of 3-phosphoglycerate to 2-phosphoglycerate and subsequently to phosphoenolpyruvate, via enolase. Thus, for every glucose molecule that has fermented, the net gain is two molecules of ATP.

Stage III serves to recycle the two molecules of NADH, produced in Stage II, back into its oxidized form (NAD^+), so that it is once again available to accept electrons from the phosphorylation of glyceraldehyde-3-phosphate. Different organisms complete this fermentation in a variety of different ways. For example, lactic acid bacteria reduce pyruvate to lactate via lactate dehydrogenase, whereas yeasts reduce pyruvate to ethanol and CO_2 via acetaldehyde, via the sequential action of pyruvate decarboxylase and alcohol dehydrogenase. As well as restoring redox balance through NAD^+/NADH cycling, Stage III also enables atomic balance to be achieved, where the end products of the fermentation, e.g., 2 ethanol ($\text{C}_2\text{H}_5\text{OH}$) + 2CO_2 , equal that of the starting substrate, i.e., glucose ($\text{C}_6\text{H}_{12}\text{O}_6$). The end products of fermentation are disposed of from the cell as waste. Organisms which produce a single end product, e.g., lactic acid, from glycolysis are known as homofermenters. Heterofermenters on the other hand produce multiple end products from glycolysis, e.g., acetate, ethanol, formate and CO_2 .

Other fermentative pathways also exist which utilize glucose as the exogenous electron donor. These are the heterolactic, or phosphoketolase, pathway and the Entner-Doudoroff pathway. The key enzymes involved in these pathways are phosphoketolase and 2-keto-3-deoxy-6-phosphogluconic acid, respectively. The main difference between these pathways and glycolysis is the timing of NAD-mediated oxidations. These occur before the substrate is cleaved during the phosphoketolase and Entner-Doudoroff pathways and generate 1 ATP, whereas in glycolysis, these occur after substrate cleavage, generating 2 ATP. The phosphoketolase pathway is prominent in probiotic lactic acid bacteria such as *Lactobacillus* and *Leuconostoc*, whereas the Entner-Doudoroff pathway dominates in some pathogenic bacteria such as *Pseudomonas aeruginosa* and *Vibrio cholerae*.

Fig. 2 Glycolysis, or the Embden-Meyerhof pathway. The sequence of enzymatic reactions involved in the generation of pyruvate from glucose. The key enzymes involved are: (1) hexokinase, (2) isomerase, (3) phosphofructokinase, (4) aldolase, (5) glyceraldehyde-3-phosphate dehydrogenase, (6) phosphoglycerokinase, (7) phosphoglyceromutase, (8) enolase, and (9) pyruvate kinase. Note that two molecules of glyceraldehyde-3-phosphate are produced after step 4 therefore the subsequent sequence runs twice, ultimately forming two molecules of pyruvate. The overall reaction as well as a summary of the number of ATP molecules consumed and generated is also provided.

Bacteria are also able to metabolize longer chained derivatizations of glucose or other carbohydrates. Examples of these are nondigestible oligosaccharides including fructooligosaccharide (a chain of fructose residues bound terminally to glucose) and galactooligosaccharide (a chain of galactosyl residues bound terminally to glucose), which are hydrolyzed to their constituent monosaccharides, thus releasing glucose. Oligosaccharides, found in bananas, garlic and onions, are known for the prebiotic potential, meaning that they are selectively metabolized by probiotic bacteria found in the human colon. Dominance of probiotic bacteria in the gut is linked with several host advantages including the breakdown of indigestible fibers to usable nutrients, modulation of the immune system and inhibition of pathogenic microbes.

Aerobic respiration

Respiration is a process whereby glucose can undergo complete oxidation to CO_2 . This is facilitated by the presence of a final electron acceptor. The formation of ATP coupled to an electron transport chain is known as oxidative phosphorylation. In aerobic

respiration, the final electron acceptor is O₂. Other anaerobic forms of respiration also exist and will be discussed in “*Anaerobic respiration*” section. The theory of ATP synthesis driven by the proton motive force or “chemiosmosis” was one of the most monumental scientific discoveries of the 20th century. Its founder, Peter Mitchell, was awarded the Nobel Prize for Medicine (Mitchell, 1961). It involves the sequential transfer of electrons from an organic substrate to the final electron acceptor across a semi-permeable membrane. Here, each electron transport step results in the synthesis of ATP, establishing a highly energized state. Electron transport relies on the presence of electron carriers which span the cell membrane, allowing separation of electrons and protons on the inside and outside, respectively. In Gram positive bacteria, these protons are released into the environment, whereas in Gram negative bacteria they accumulate in the periplasm. This differential separation of protons and electrons results in a pH gradient, whereby the outside of the membrane is slightly acidic, or electro-positive, when compared to the inside, which is electro-negative. This generates an electrochemical potential across the membrane, and the resulting electrical energy is conserved by the cell in the form of ATP.

Aerobic respiration in heterotrophic organisms can be summarized as per Eq. (5).

Here, glucose is completely oxidized to the given reaction products. The net energy yield from the oxidation of a single glucose molecule is 38 molecules of ATP. This equates to the generation of approximately 380,000 calories (cal), as each ATP molecule corresponds to 10,000 cal mol⁻¹. Thermodynamically, this net calorific value is much higher (around 688,000 cal), however the vast majority of this energy (around 308,000 cal) is lost as heat, making the process of cellular respiration approximately 55% efficient (Jurtshuk, 1996). The above equation is however a highly simplified representation of the total dissimilatory reaction, which typically involves three fundamental biochemical steps. The first of these is glycolysis, described previously, yielding 4 ATP molecules. The second and third steps, the Krebs cycle and the Electron Transport Chain (ETC), respectively are described in the subsequent sections.

The Krebs cycle

The second step in respiration is the Krebs cycle (also known as the tricarboxylic acid or citric acid cycle, see Fig. 3). It involves a series of oxidative decarboxylation steps, beginning in bacteria with acetyl -CoA and results in complete oxidation of the starting substrate (i.e., glucose) coupled with release of CO₂. In addition, this metabolic cycle results in the generation of 10 pairs of electrons, which feed into the final step of respiration, the ETC. Each electron pair produced results in the generation of 2–3 molecules of ATP through the ETC. As two molecules of the intermediary substrate pyruvate are formed during glycolysis, this cycle runs twice for every molecule of glucose which is oxidized.

The first step of this pathway begins with the decarboxylation of pyruvate to the Krebs cycle starting molecule, acetyl-CoA. This itself is a three-step reaction, whereby (1) a carboxyl group is removed from pyruvate to produce CO₂ and a hydroxyethyl group bound to the enzyme pyruvate dehydrogenase, (2) an acetyl group is formed from the oxidation of the hydroxyethyl group, and the resulting electrons are transferred to NAD⁺, forming NADH + H⁺, (3) this acetyl group is then transferred from the enzyme to coenzyme A (CoA) resulting in the formation of acetyl-CoA. There are two things to note from this initial step of the Krebs cycle: (1) the decarboxylation of pyruvate represents the first of six decarboxylations within this reaction cycle, one for each of the six carbon atoms present in the initial substrate, glucose, facilitating its complete oxidation; (2) the high energy electrons, stored within the eight NADH molecules generated will be used later to generate ATP via the ETC.

Next, CoA is released from the acetyl group following its condensation with oxaloacetate to form the tricarboxylic acid, citrate. This is the first stable intermediary of the Krebs cycle, which is initially isomerized to isocitrate, before being oxidized and decarboxylated to α-ketoglutarate. The oxidation of α-ketoglutarate to succinyl CoA via α-ketoglutarate dehydrogenase is analogous to the action of pyruvate dehydrogenase described previously, involving CoA and NAD⁺. The conversion of succinyl CoA to succinate completes the decarboxylation of pyruvate, and also yields a molecule of guanosine triphosphate (GTP, equivalent to ATP), via succinyl-CoA synthetase. The remaining steps of the Krebs cycle result in the regeneration of oxaloacetate (via fumarate and malate) and complete the oxidation of succinate.

Both the Krebs cycle and glycolysis are amphibolic, meaning that a number of the intermediary molecules produced may be used for assimilative (biosynthetic) pathways (see “*Anabolic pathways: Biosynthesis*” section), as well as the dissimilative pathway outlined here.

Electron transport chain

The ETC is the final step of respiration where electrons are transferred through a series of oxidation-reduction reactions (see Fig. 4). Here a series of membrane-associated proteins and mobile accessory carriers transport electrons from the substrate and along the plasma (in prokaryotes) or mitochondrial membrane (in eukaryotes) to the final electron acceptor. In eukaryotic micro-organisms the substrate for this process is usually NADH + H⁺, succinate or fatty acids. In addition to these substrates, bacteria can also oxidize a larger selection of low redox potential substrates such as H₂, glutamate, α-glycerophosphate, lactate, malate and formate (Jurtshuk, 1996) via non-pyridine nucleotide-dependent pathways. The electron carriers themselves are separated into four major classes: cytochromes, flavoproteins, iron-sulfur proteins and quinones, and are more varied in prokaryotes than in eukaryotes. These electron carriers are responsible for the sequential removal of electrons from the substrate at the various steps, due to their redox potential. In order to accept electrons, the protein or carrier must be more electronegative (or have a lower E₀') than the electron

Fig. 3 The Krebs, or citric acid, cycle. Pyruvate, derived from glycolysis, is firstly converted into acetyl-CoA (2-C) which is subsequently condensed with oxaloacetate (4-C) to form the 6-C compound citrate. This is cycled back to oxaloacetate via a series of reactions which form CO₂ (as a waste product) as well as NADH and FADH. Note that this cycle runs twice for every molecule of glucose which undergoes oxidation during glycolysis, as two molecules of pyruvate are formed. Although some ATP is generated via the GTP derived from the Krebs cycle, most of the ATP generated during aerobic respiration comes from oxidative phosphorylation. The NADH and FADH generated during the Krebs cycle fuels the electron transport chain which drives this process, ultimately producing 38 molecules of ATP. The key enzymes involved are: (A) pyruvate dehydrogenase; (B) citrate synthase; (C) isocitrate dehydrogenase; (D) α-ketoglutarate dehydrogenase and succinyl-CoA synthetase; (E) succinic dehydrogenase; (F) fumarase; (G) malate dehydrogenase.

Fig. 4 Oxidative phosphorylation in eukaryotes. ATP synthesis is coupled to the sequential transfer of electrons via an electron transport chain from NADH or FADH₂ to oxygen. This process is facilitated by a series of electron carriers, which also serve to establish the proton motive force by translocating protons outside the membrane. This generates an electrochemical gradient which fuels the final ATP synthesis step. Abbreviations are as follows: complex I, NADH coenzyme Q reductase; complex II, succinate dehydrogenase; complex III, cytochrome *bc*₁; complex IV, cytochrome *c* oxidase; complex V, F₀F₁ ATP synthase; CoQ, coenzyme Q; cytC, cytochrome *c*. The subunits (a, b, c, α, β, δ, ε and γ) which make up the F₀ and F₁ units of complex V are also indicated.

donor, e.g., NADH and FADH₂. Electrons therefore enter this chain at low E_0' (electronegative) and exit at a higher E_0' (electro-positive). This drop in E_0' supplies energy to drive oxidative phosphorylation which results in the generation of ATP. Essential to this process is a final electron acceptor which is derived from outside the cell (e.g., O₂ in aerobic respiration and S, SO₄, NO₂ or NO₃ in anaerobic respiration) and an ATP synthetase (ATPase) which spans the membrane. Two protons are consumed by this enzyme, which are shuttled from the F₀ to the F₁ units where the phosphorylation of ADP to ATP takes place as per Eq. (6).

The ATPase serves as a channel for H⁺ to flow across the membrane in a process called chemiosmosis, where these ions flow along their electrochemical gradient from a region of higher concentration (outside membrane) to a region of lower concentration (inside membrane). The potential energy stored within this electrochemical gradient serves as a second mechanism for ATP synthesis.

Inhibitors and uncouplers are chemicals that can be used to study the ETC and oxidative phosphorylation, respectively. Inhibitors prevent the establishment of the proton motive force by blocking electron flow. Cyanide (CN⁻) and carbon monoxide (CO) are examples of inhibitors which bind to a-type cytochromes such as those forming Complex IV. These inhibit terminal electron transfer to O₂ or compete with O₂ for binding to Complex IV. Uncouplers prevent ATP synthesis without affecting the ETC. Dinitrophenol (DNP) is an example of an uncoupler which as a protonophore, allowing protons to leak across the membrane, thereby bypassing ATP synthase. This greatly reduces the efficiency of oxidative phosphorylation and the excess energy accumulated via the ETC is lost as heat.

Electron transport chain in eukaryotes

In aerobic unicellular eukaryotes which possess traditional mitochondria (e.g., *Acanthamoeba* and *Naegleria*), the ETC is comprised of four complexes (I-IV), each of which are composed of multiple proteins (see Fig. 4). Each complex either receives electrons from a coenzyme carrier or directly from one of the other complexes. These proteins sit on the inner mitochondrial membrane and can pump protons extracted from the oxidized substrate into the intermembrane space. This establishes the electrochemical gradient (ΔpH) and largely contributes towards the mitochondrial membrane potential ($\Delta\Psi_{\text{M}}$) across the inner mitochondrial membrane, which is important for the final ATP synthesis step. The ETC begins with **complex I** (NADH coenzyme Q reductase, also known as NADH:quinone oxidoreductase). This enzyme removes 2e^- from NADH, the main electron carrier derived from the Krebs cycle, and subsequently transfers them to coenzyme Q (ubiquinone), producing the reduced product ubiquinol (QH₂). This reaction is facilitated by FMN, which also accepts two protons from the dissociation of water in the cytoplasm, becoming its reduced form FMNH₂. Each electron from the FMNH₂ is transferred to an iron-sulfur (Fe-S) cluster before being passed on to ubiquinone (Q). This releases two protons which are translocated into the intermembrane space, and recycles FMNH₂ back to its oxidized form, FMN. The transfer of electrons from the Fe-S cluster to Q is a two-step reaction, whereby transfer of the first electron results in the formation of a semiquinone intermediate (the free radical form of Q), and transfer of the second electron results in reduction of this semiquinone to QH₂. This process, known as the Q cycle, results in four H⁺ being translocated across the membrane. The energy

needed to actively transport these protons into the intermembrane space is derived from the electron current which is established through the continuous oxidation and reduction of electrons across the complex at a ratio of 4H^+ per 2e^- derived from NADH.

The resulting QH_2 is mobile within the membrane and is also capable of bypassing complex I by receiving electrons from succinate via **complex II** (succinate dehydrogenase or succinate-CoQ reductase) or other electron donors (e.g., fatty acids and glycerol-3-phosphate). All such electrons are transferred to Q via FADH_2 . The pathways of electron transport through complex II is similar to that of complex I, but without the translocation of protons across the membrane.

The electrons are next transferred from QH_2 in **complex III** (cytochrome bc_1 or CoQH_2 -cytochrome c reductase) to two molecules of cytochrome c , which is water soluble and located within the intermembrane space. Complex III is composed of several proteins containing heme or metal centers, including b-type hemes (b_L and b_H), a c-type heme (c_1) and Fe-S protein ("Rieske"). Complex III is conserved across most respiring organisms. The transfer of electrons to cytochrome c by complex III is coupled with the translocation of four protons, of which two are used to reduce QH_2 to quinol and a further two are released from two molecules of ubiquinol (see Eq. 7).

Complex IV (cytochrome c oxidase) transfers four electrons (derived from four molecules of cytochrome c) to O_2 , reducing it to two molecules of H_2O . This complex is composed of cytochromes a and a_3 , where the latter acts as the terminal oxidase. During this process, eight protons are taken from the mitochondrial matrix, four of which are used to produce H_2O and the remaining four are pumped into the intermembrane space. This complex is comprised of several copper and heme groups, including Fe^{3+} . The latter makes complex IV a target for CN^- poisoning, which blocks electron transport thereby depleting ATP synthesis, resulting in cell death. The oxidase test is a standard biochemical test for the identification of microbes which possess cytochrome c oxidase. Here, the reagent, tetra-methyl- p -phenylenediamine dihydrochloride (e.g., Kovac's oxidase reagent) acts as an artificial electron acceptor for the oxidase enzyme inducing a color change from clear to purple, indicating an oxidase positive result. *Pseudomonas*, *Campylobacter*, *Vibrio* and *Neisseria* species are examples of oxidase positive organisms.

The final step in respiration involves coupling the ETC, and the resulting electrochemical gradient, to oxidative phosphorylation via the F_0F_1 ATP synthase (or **complex V**). This culminates in the synthesis of ATP, which is a reversible reaction depending on the application. The F_0 part of the enzyme spans the membrane providing a channel through which H^+ ions can flow back into the mitochondrial matrix. The protons move sequentially through the α , β and δ subunits of the F_0 unit. Once this revolution is complete, the protons are released back into the mitochondrial matrix. This process releases the free energy derived from the ETC, which is used by the F_1 component of complex V, located at the matrix end of the complex, to drive ATP synthesis.

The overall structure of ATP synthases is conserved across the domains of life, which suggests an early evolutionary origin in biological energy conservation. This structure allows the complex to behave as a motor (see complex V structure in Fig. 4). The flow of protons through subunit a of F_0 causes the c proteins to rotate. This torque is transmitted to F_1 via the coupled rotation of the $\gamma\epsilon$ subunits. These subunits also transfer energy to F_1 which is converted to potential energy via conformational changes of the β subunits. This allows the binding of $\text{ADP} + \text{P}_i$, the substrates for ATP synthesis. When this is complete, the β subunits return to their original conformation. The ATPase usually consumes 3H^+ for every ATP produced. As mentioned, the reversibility of the F_1/F_0 motor is facilitated by the hydrolysis of ATP, which induces the torque to allow the γ subunit to rotate in the opposite direction. Here, protons are also translocated in the opposite direction, i.e., inside the cytoplasm or mitochondrial matrix, thus generating the proton motive force, rather than dissipating it. This explains why some anaerobic microbes which cannot undergo oxidative phosphorylation also synthesize ATPase and use this for important cellular processes such as motility and transport.

Electron transport chain in prokaryotes

As discussed above, prokaryotes can use a wide variety of electron donors, which enter the ETC at various levels, depending on the energy source of that organism. Organotrophs typically use NADH or succinate, whereby electrons enter the ETC through complexes analogous to complex I and II of mitochondria, respectively. Alternative dehydrogenases are required to process electron donors such as H_2 , formate, lactate and glyceraldehyde-3-phosphate. Many of these dehydrogenases are inducible depending on the metabolic requirements of the organism and their external environment. In terms of quinone carriers, many bacteria use ubiquinone as used by eukaryotic mitochondria. Others employ menaquinone (vitamin K_2). Some archaea, e.g., *Sulfolobus* spp., use caldariellaquinone. The choice of quinone depends on the redox potential of the electron donor. In bacteria, the ETC components sit on the plasma membrane, therefore a proton gradient must be established between the cytoplasm and periplasmic space to provide the energy for oxidative phosphorylation to occur. Bacteria must therefore also possess proton pumps, which maintain this gradient, in much the same way as their eukaryotic counterparts. Membrane-bound dehydrogenases, oxidases and reductases serve as bacterial proton pumps. The bacterial cytochrome bc_1 for example is very similar to complex III found in mitochondria, however it is not ubiquitous among all bacteria (absent from *E. coli*). In lithotrophic bacteria, electrons derived from inorganic electron donors (e.g., nitrite and ferrous iron) may enter the ETC at the level of the mobile electron carriers, i.e., cytochromes or quinones. This means that the electron donor has a reduced E_0' as compared to NADH, therefore the ETC must firstly run in reverse in order to generate this higher-energy molecule. Bacteria have two classes of oxidases. Class I oxidases are comprised of cytochrome oxidases, using O_2 as the terminal electron acceptor, whereas Class II oxidases are quinol oxidases, which use a wide range of final electron acceptors.

Anaerobic respiration

Anaerobic respiration occurs when an energy-yielding electron transport chain terminates with any final electron acceptor other than O_2 . It is important to note, however, that facultative anaerobes growing in an aerobic environment invariably use O_2 as the terminal electron acceptor, as this produces the most energy via the Gibbs free energy change. Many of the key enzymes involved in anaerobic respiration are oxygen-sensitive, rendering such pathways inactive in the presence of O_2 . Obligate anaerobes are not able to use O_2 , therefore rely solely on the availability of alternative electron acceptors. The terminal reductases of anaerobic bacteria are tailored to their terminal electron acceptor (see Fig. 1). This section outlines four key pathways of anaerobic respiration which have evolved in different microbes, these are methanogenesis, acetogenesis, denitrification/nitrate reduction and sulfate reduction.

Methanogenesis

Methane (CH_4) production through anaerobic respiration is reserved to a specialist group of strictly anaerobic archaea, known as methanogens. The initial substrate for this reaction is CO_2 and this is ultimately reduced to CH_4 via a series of reactions involving two types of cytochromes, classified according to their role in methanogenesis (Madigan and Martinko, 2006; see Fig. 5), as per Eq. (8).

The first class of cytochromes carries the C_1 unit from CO_2 to the end-product. The second class provide the electrons required to perform the necessary redox reactions. The electrons required to reduce CO_2 to CH_4 are typically sourced from H_2 , however CO , formate and some organic compounds (e.g., methanol), are also known to perform this function. The initial step of methanogenesis involves the coenzyme methanofuran. This binds CO_2 to the amino nitrogen atom attached to its furan ring, and using H_2 , reduces CO_2 to formyl. The methanogenic coenzyme, methanopterin, then carries the C_1 unit from methanofuran, at which point it is dehydrated to methylene and subsequently reduced to a methyl group (CH_3). The F_{420} coenzyme (a flavin derivative, structurally similar to FMN) acts as an electron donor during these steps. From methanopterin, the methyl group is then transferred to coenzyme M. Whilst bound to CoM, the CH_3 is reduced to CH_4 via methyl reductase enzyme complex. Coenzyme B and F_{430} play a key role during this terminal step of methanogenesis. The CH_3 group is removed from CoM and binds to the nickel ion (Ni^{2+}) group of coenzyme F_{430} . Electrons from CoB are then used to reduce the Ni^{2+} - CH_3 complex, resulting in the generation of CH_4 , as

Fig. 5 Methanogenesis. The sequential series of enzymatic reactions which leads to the formation of methane (CH_4) from CO_2 using H_2 as an electron donor. The reduced C-atom is indicated in green and electron sources are indicated in blue. Abbreviations are as follows: MF, methanofuran; MP, methanopterin; CoM, coenzyme M; F_{420}^{red} , reduced coenzyme F_{420} ; F_{430} , coenzyme F_{430} ; CoB, coenzyme B. Adapted from Madigan MT and Martinko JM (2006). *Brock Biology of Microorganisms*, 11th edn., pp. 566. Upper Saddle River, NJ: Pearson Education, Inc., Fig. 17.44.

well as a CoM and CoB disulfide complex (CoM-S—S-CoB). Coenzymes F_{420} , M and B are recycled through reduction by H_2 . Energy conservation in methanogenesis is facilitated during the reduction of the CoM-S—S-CoB complex cytochromes to CoM-SH and CoB-SH. This is carried out by cytochrome F_{420} and heterodisulfide reductase. The latter is an enzyme which spans the membrane and generates a proton motive force by extruding protons across the membrane. This is linked to an ATPase. ATP is produced at a rate of approximately 1 ATP molecule for every reduction of CO_2 to CH_4 via H_2 . When methanol is the substrate for methanogenesis, methyl groups are instead donated to a corrinoid protein (containing a porphyrin-like ring and Co), which transfers the CH_3 group to CoM. A corrinoid protein also plays a similar role when acetate is the substrate. In this reaction, acetate firstly undergoes activation to acetyl-CoA and carbon monoxide dehydrogenase from the acetyl-CoA pathway. When methanol is the substrate, some of this compound must firstly be oxidized to CO_2 in order to supply the electrons required for reduction of CH_3 to CH_4 . The energy required for methyl oxidation is provided by a second type of ATPase powered by a sodium (Na^+) motive force, rather than H^+ .

Acetogenesis

Like the methanogens, homoacetogens also use CO_2 and H_2 as an electron acceptor and donor, respectively. These organisms use the acetyl-CoA pathway to reduce CO_2 to acetate ($C_2H_3O_2^-$) as per Eq. (9) and detailed further in Fig. 6 (Madigan and Martinko, 2006).

During this process, the two molecules of pyruvate synthesized during glycolysis are converted to 2 molecules of $C_2H_3O_2^-$, in addition to two molecules of CO_2 and 4 hydrogen atoms. The $2CO_2$ molecules are reduced to the methyl and carbonyl groups of acetate using the electrons derived from the $4H$ atoms, as well as four additional electrons derived from the $2NADH + H^+$ also generated during glycolysis. Coenzyme tetrahydrofolate (THF) is involved in the generation of the CH_3 group of acetate from one CO_2 molecule, which is firstly converted to CHO-THF (at the expense of one molecule of ATP) and then CH_3 -THF before being transferred to an enzyme containing a vitamin B_{12} cofactor. The carbonyl group (CO) of acetate, derived from the second CO_2 molecule, is synthesized via the action of carbon monoxide dehydrogenase. This contains a number of metal cofactors, Ni, Fe and Zinc (Zn), which facilitate its catalytic function. In the final step of the pathway the CH_3 group is combined with the CO group, facilitated by coenzyme A to form acetyl-CoA. This step helps to establish a Na^+ motive force across the cytoplasmic membrane, which is coupled to an ATPase, forming one molecule of ATP. An additional ATP molecule is produced during the conversion of acetyl-CoA to acetate.

A wide variety of alternative electron donors are also available for acetogenesis, e.g., C_1 compounds, organic/amino acids, sugars and some N-bases. In addition to CO_2 , many homoacetogens are also able to reduce NO_3^- and $S_2O_3^{2-}$. Most acetate-excreting homoacetogens are Gram positive bacteria, many of which belong to the genus *Clostridium*. *Clostridium difficile*, for example, is an opportunistic pathogen associated with hospital-acquired antibiotic-associated diarrhea. In addition to its role in energy conservation, many homoacetogens also use this pathway for autotrophic growth, e.g., sulfate-reducing bacteria, in addition to the methanogens mentioned previously. In some acetotrophic methanogens and sulfate-reducing bacteria this pathway runs in the reverse direction, whereby acetate is oxidized to CO_2 .

Fig. 6 Acetogenesis. The sequential series of enzymatic reactions which leads to the formation of acetate ($C_2H_3O_2^-$) from CO_2 via acetyl-CoA, using H_2 as an electron donor. The reduced C-atom is indicated in green and electron sources are indicated in blue. Abbreviations are as follows: THF, tetrahydrofolate; B_{12} , vitamin B_{12} . Nitrate reduction and denitrification

Nitrogen gas (N_2), ammonia (NH_3) and nitrate (NO_3^-) are among the most commonly used alternative electron acceptors among anaerobes. Reduction of NO_3^- to NH_3 or N_2 involves a series of sequential redox reactions involving an ETC (Madigan and Martinko, 2006). The enzymes which facilitate this process are usually found in different microorganisms which live in the same niche and thus live synergistically. The opportunistic pathogen *Pseudomonas stutzeri*, however, possesses the full repertoire of enzymes necessary to perform the entire process of NO_3^- reduction to N_2 under aerobic conditions. Denitrification is the loss of the end products derived from NO_3^- reduction, e.g., nitric oxide (NO), nitrous oxide (N_2O) and N_2 (which are all gaseous) to the environment. This represents the major route of biological N_2 formation and is of great environmental significance. This is because it involves the removal of fixed nitrogen sources, nutrients which are vital to plants and therefore agriculture, and can result in accumulation of greenhouse gasses. The entire process of nitrate reduction in microbes, as well as the enzymes involved at each step in various organisms are summarized in Fig. 7.

Due to the lower redox potential of the NO_3^-/NO_2^- couple (+0.43 V, see Fig. 1) a smaller amount of ATP is generated via ATPase. The complete dissimilation of NO_3^- to N_2 yields a greater amount of ATP due to the ability of NO reductase to translocate additional protons within the ETC. Most denitrifying bacteria are facultative anaerobes belonging to the Proteobacteria phylum (e.g., *Escherichia coli*). Other forms of anaerobic respiration found within members of this phylum involve the use of ferric iron (Fe^{3+}) and organic molecules as final electron acceptors, in addition to fermentation.

Sulfate reduction

Dissimilative sulfate (SO_4^{2-}) reduction is limited to the sulfate-reducing bacteria (SRB, e.g., *Desulfovibrio* spp. found in the intestine) in addition to *Archaeoglobus*, an archaeon. The members of this group are ubiquitous in nature and excrete H_2S as a product of SO_4^{2-} reduction. The reduction potential of SO_4^{2-} ($E_0' = +6$) as an electron acceptor is lower than that of O_2 and NO_3^- , thereby yielding less ATP see Fig. 1). A range of electron donors are employed by SRB to complete SO_4^{2-} reduction, these include H_2 , lactate, pyruvate, alcohols (e.g., ethanol), fumarate, malate and long-chain fatty acids. The reaction is summarized in Fig. 8 (Madigan and Martinko, 2006). Firstly, the sulfate ion requires ATP activation due to its stability. ATP sulfurylase catalyzes this reaction which results in the formation of adenosine phosphosulfate (APS). APS reductase then reduces the SO_4^{2-} group in APS to sulfite (SO_3^{2-}), the first product of SO_4^{2-} reduction, releasing AMP. Next, SO_3^{2-} reductase reduces SO_3^{2-} to sulfide (HS^-). A proton motive force is established via electron transport during SO_4^{2-} reduction, which drives ATP synthesis via an ATPase. Cytochrome C_3 plays a key role as an electron carrier, accepting 8 electrons from hydrogenase and transferring them to a cytochrome complex (Hmc). All three proteins are located on the periplasmic side of the membrane. Electrons are shuttled across the membrane from Hmc to an Fe-S protein located

Fig. 7 A summary of the steps involved in dissimilative nitrate reduction to N_2 . The reduced N-atom is indicated in orange. The final three steps result in the release of gaseous products in a process called denitrification. Adapted from Madigan MT and Martinko JM (2006). *Brock Biology of Microorganisms*, 11th edn., pp. 559. Upper Saddle River, NJ: Pearson Education, Inc., Fig. 17.36.

Fig. 8 A summary of the steps involved in dissimilative sulfate reduction to hydrogen sulfide (H_2S) via adenosine 5'-phosphosulfate, a derivative of ADP. The reduced S-atom is indicated in red. Adapted from Madigan MT and Martinko JM (2006). *Brock Biology of Microorganisms*, 11th edn., pp. 561. Upper Saddle River, NJ: Pearson Education, Inc., Fig. 17.38.

on the cytoplasmic side, which in turn supplies these electrons to APS reductase and sulfate reductase within the cytoplasm. Externally sourced H_2 or that generated through the oxidation of organic acids, e.g., lactate to acetate (via pyruvate) through lactate dehydrogenase, can be utilized as electron donors. When H_2 is the electron donor, around one molecule of ATP is generated for every SO_4^{2-} reduction to HS^- . When lactate or pyruvate are electron donors, an additional ATP is produced during the conversion of pyruvate to acetate and CO_2 via acetyl CoA or acetyl-phosphate (see Acetogenesis section).

Some SRB, such as *Desulfovibrio sulfodismutans*, are capable of sulfur disproportionation. This involves splitting a compound, e.g., thiosulfate ($\text{S}_2\text{O}_3^{2-}$), into one more oxidized product, e.g., SO_4^{2-} , and another more reduced product, e.g., H_2S , than the original substrate. The initial substrate is usually a sulfur compound of intermediate oxidation state, additional examples of which include SO_3^{2-} and elemental sulfur (S^0). This allows SRB to coexist with chemolithotrophic bacteria which produce these sulfur intermediates through the oxidation of H_2S . The autotrophic SRB *Desulfotignum phosphitoxidans* is a strict anaerobe which uses phosphite (HPO_3) and CO_2 as its sole carbon and energy source, respectively. This bacterium couples SO_4^{2-} reduction to HPO_3 oxidation, producing phosphate (HPO_4^{2-}) and HS^- chemolithotrophically.

Anabolic pathways: Biosynthesis

Monomers, hexoses such as glucose and its six-carbon sugar derivatives, are the building blocks of the polymers required for cellular growth. The majority of the ATP molecules synthesized during the catabolic processes described above are directed towards protein and nucleic acid synthesis. A comparatively smaller amount of energy is required for lipid and polysaccharide biosynthesis. In the absence of monomers in their surrounding environment, microbes must synthesize these building blocks from simpler constituents through anabolic processes.

Gluconeogenesis is an example of an anabolic process, whereby compounds containing 2–5 carbon atoms are used as substrates to synthesize glucose. In general, the reverse steps of glycolysis are performed from phosphoenolpyruvate, which can be synthesized from oxaloacetate derived from the Krebs cycle. For polysaccharide biosynthesis activated forms of glucose, uridine diphosphoglucose (UDPG) or adenosine diphosphoglucose (ADPG), are used as starting material. UDPG is a precursor for *N*-acetylglucosamine or *N*-acetylmuramic acid, which are present in peptidoglycan or lipopolysaccharide in the Gram-negative cell wall. ADPG is a precursor for glycogen, used in long-term energy storage. Pentose (5-carbon) sugars, e.g., ribose and deoxyribose, are required for nucleic acid synthesis. For this a carbon atom is removed from a hexose sugar and released as CO_2 . The NADPH-dependent ribonucleotide reductase enzyme reduces ribose to deoxyribose, which are precursors of RNA and DNA, respectively.

Synthesis of amino acids, the building blocks of proteins and nucleic acids, consist of complex, multi-step processes. Most of the carbon skeleton required to synthesize all amino acids are derived from either glycolysis or the Krebs cycle. The amino group is derived from a source of inorganic nitrogen in the environment. Glutamate dehydrogenase and glutamate synthase, for example,

incorporate NH_3 into the amino acids glutamate or glutamine, respectively. These amino acids can then shuttle NH_3 through transaminase (via oxaloacetate) or aminotransferase (via α -ketoglutarate) reactions into carbon skeletons which undergo further biosynthetic reactions culminating in the synthesis of all 21 amino acids which form the building blocks of proteins in the cell. Purines and pyrimidines, the monomeric precursors of nucleotides, are constructed from several different carbon and nitrogen sources. Inosinic acid and uridyate are the precursors for purine (i.e., adenine and guanine) and pyrimidine (i.e., cytosine, thymine and uracil) nucleotide synthesis, respectively.

Fatty acids, a major component of lipids in bacteria and eukaryotes, are synthesized via an acyl carrier protein (ACP). This holds the fatty acid chain in position and binds with a 3-carbon compound, malonate, which donates 2-carbon atoms at a time to build the chain. The remaining carbon atom is released as CO_2 . ACP releases the saturated (even carbon number chain length) fatty acid when the desired chain length has been achieved (around C_{12} – C_{20} in bacteria). Unsaturated (odd carbon number chain length) fatty acids are synthesized through the desaturation of a saturated fatty acid and contain at least one double bond. Different microbial species vary in their fatty acid composition and this is temperature-dependent: the higher the temperature, the longer the chain. Lipid assembly in bacteria and eukaryotes involves the addition of glycerol to fatty acids through esterification. Complex lipids may also have phosphate, ethanolamine or a sugar attached to one of the glycerol carbon atoms. Instead of fatty acids, the lipids of archaea contain phytanyl sidechains. In all cases however, the glycerol head is hydrophilic and the tail is hydrophobic. These characteristics allow phospholipids, where the glycerol backbone is bound to a phosphate group and two fatty acid tails, to play a key structural role in cellular membranes.

Conclusion

This chapter summarizes key metabolic pathways present in medically relevant microorganisms. It is important to note, however, that, rather than being passive players, many microbes can remodel their metabolism in response to the host microenvironment. This can facilitate evasion of the immune system (Traven and Naderer, 2019), antibiotic resistance (Davies, 1994) and out-competing rivals (Bauer et al., 2018), ultimately facilitating growth and survival in the host. Microbes are very seldom found as singular entities. Their existence relies on complex metabolic interactions with other microbial species, their host and environment. Understanding this complex web of interactions is facilitated by metabolomics, the study of substrates and products of metabolism (or metabolites). Techniques for characterizing the metabolome include nuclear magnetic resonance (NMR spectroscopy) and chromatography coupled to mass spectrometric detection, e.g., gas chromatography-mass spectrometry (GC-MS, David and Rostkowski, 2020). The metabolic fingerprint generated through metabolomic techniques is thought to be the closest representation of phenotype as it reflects the biochemical activity of a cell or particular biological niche. This approach therefore has great potential in enhancing our understanding of cellular processes in normal and diseases states, biomarker discovery and personalized medicine (Singh, 2020).

Introduction

Global burden of human pathogenic fungi

Over one billion people worldwide suffer from mycoses. These range from superficial, non-life-threatening infections to potentially mortal chronic and invasive diseases that result in approximately 1.6 million deaths each year (Bongomin et al., 2017). Among the millions of fungal species only around 300 are capable of causing human disease and four genera are responsible for 90% of deaths: *Candida*, *Aspergillus*, *Cryptococcus* and *Pneumocystis* (Taylor et al., 2001; Wu et al., 2019; Brown et al., 2012). The variety of niches within the human body in which fungi are able to grow is astounding, and indeed mycotic infections have been described in every organ system (Denning, 1998; Spampinato and Leonardi, 2013; Urs et al., 2016; Corr, 2011; Gavito-Higuera et al., 2016; Kuttin, 2009; de Moraes et al., 2011; Lionakis et al., 2008). *Aspergillus* and *Pneumocystis* predominantly infect the respiratory system (Brown et al., 2012; Kosmidis and Denning, 2015) but both may also have extrapulmonary manifestations; for example *Aspergillus* is one of the dominant causes of fungal keratitis (Xie et al., 2008; Karam and Mosadegh, 2014). Similarly, *Cryptococcus* infection commences in the lungs, but this fungal pathogen can reach almost every organ by hematogenous dissemination, with infection of the central nervous system being most common and the leading cause of mortality (Kwon-Chung et al., 2014). *Pneumocystis jirovecii* has a highly compacted genome with substantial reduction of metabolic pathways, which explains its nature as an obligate fungal parasite that can only thrive in human lungs (alveoli), where it causes pneumonia in immunodeficient patients (Brown et al., 1980;

Skalski et al., 2015; Nevez et al., 2020). In contrast, *Candida* is a generalist that can thrive as a commensal in niches throughout the body, such as the gastrointestinal tract, vaginal mucosa or the buccal cavity. Under certain circumstances it can cause mucosal infections, which affect millions, and invasive candidiasis, the most common type being candidemia or *Candida* bloodstream infection (Köhler et al., 2015; Bongomin et al., 2017). Worryingly, the incidences of fungal invasive infections are increasing due to the rise of the at-risk populations, and, despite of the availability of antifungal drugs, the mortality rates are intolerably high (Brown et al., 2012; Bongomin et al., 2017; Bitar et al., 2014). This is usually attributed to delayed diagnosis, inappropriate antifungal therapy and emergence of resistance, but also other factors such as high fungal burden, underlying disease, the antifungal pharmacokinetics and pharmacodynamics and toxicity (Fisher et al., 2018; Pagano and Mayor, 2018). This chapter will provide a broad overview of fungal primary metabolism, a prominent source of potential molecular targets for the development of novel antifungal drugs and diagnostic biomarkers.

Importance of primary metabolism and its potential for antifungal exploitation

Primary metabolism can be defined as the group of biochemical pathways that are necessary for energy production, growth and maintenance of life in an organism. Fungi have an extremely versatile metabolism, as they can synthesize virtually all primary metabolites *de novo*, and also use a huge variety of extracellular nutritional sources. Indeed, central to the ability of fungal pathogens to colonise human tissues is their capacity to assimilate essential nutrients and to adapt to changes in nutritional availability between disparate microenvironments within the dynamic mammalian host (Mayer et al., 2013; Kronstad et al., 2012). Therefore, primary metabolism can be considered one of the most important virulence traits for fungal pathogens and its targeting is widely considered a promising strategy for the development of novel antifungals (Martin et al., 2011; Kaltdorf et al., 2016; Amich and Krappmann, 2012).

In this chapter we present a broad overview of primary metabolism in pathogenic fungi. We first explain the mechanisms of regulation and assimilation of essential nutrients. Subsequently, we give a brief overview of the metabolism of the four molecules of life (amino acids, lipids, nucleotides and sugars). We discuss the relevance of all processes for fungal pathogenesis and, furthermore, identify opportunities for the development of new therapeutics.

Macronutrients

Macronutrients or macroelements are those elements that fungi need in large amounts and are integral components of the molecules of life. Here we review the metabolism of the main macronutrients: carbon, nitrogen and sulfur.

Carbon metabolism

Carbon is a fundamental element of organic matter. In living organisms, carbon is essential for energy and macromolecule production and thus for growth. Therefore, fungi, as any other organism, must be able to assimilate it from the environment in large amounts. In order to do so, fungi have evolved signalling networks to identify and prioritize available carbon sources to ensure that the appropriate metabolic response is mounted. In particular, the system of carbon catabolite repression (CCR) inhibits metabolic pathways involved in exploiting alternative sources to guarantee the most energetically favorable source, glucose and other sugars (Ene et al., 2014), is utilized preferentially (Ruijter and Visser, 1997). This is important for pathogenic fungi, which need to acquire large amounts within mammalian hosts, where nutrient availability between and even within a niche is dynamic (Ramachandra et al., 2014). For instance, glucose concentrations in respiratory fluids, a primary site of host-pathogen interaction in many fungal infections, is estimated to be around 0.4 mM of healthy individuals, which can be increased by certain diseases and inflammation (Baker et al., 2007, 2006) and rises to about 5.5 mM in plasma (Danaei et al., 2011). However, alternative organic sources are present in host microenvironments and decision to exploit them or not is important for any pathogen's fitness. For instance, amino acids concentration in pulmonary microenvironments increase during inflammation (Lorenz and Fink, 2001; Grahl et al., 2011; Hu et al., 2010). Lactate is found at concentrations of between 0.5 and 2.2 mM in the plasma of healthy individuals and its concentration increases during inflammation as a result of its production by neutrophils (Bensel et al., 2011). Acetate is present at relatively high concentrations (10–30 mM) in the colon as it is produced by the intestinal microflora, and this correlates to concentrations of approximately 50–200 μ M in plasma (Schug et al., 2016). Importantly, proteins, such as collagen, elastin and mucins, are found across all host tissues and may be used as alternative carbon sources to support fungal growth (Ries et al., 2019; Farnell et al., 2012; Kronstad et al., 2012).

Regulation of carbon metabolism

The main mechanism that fungi use to regulate the acquisition of carbon from the environment is CCR. This system is partially regulated by a zinc finger transcription factor called CreA in *A. fumigatus* and Mig1p in *C. albicans* and *C. neoformans*, which represses the transcription of genes involved in the uptake and catabolism of alternative carbon sources when a preferable one, such as glucose, is present.

CCR has been extensively studied in the model organism *Saccharomyces cerevisiae*. In this yeast, the extracellular glucose levels are sensed through the Snf3p/Rgt2p signalling pathway (Kaniak et al., 2004). In low glucose, this pathway leads to the activation of the

AMP-activated kinase (AMPK) Snf1p, which phosphorylates Mig1p allowing release of glucose repression and expression of glucose-repressed genes. In high glucose, Mig1p remains dephosphorylated and present in the nucleus where it exerts repression, together with the Snf6p/Tup1p complex (Hedbacker and Carlson, 2008; Gancedo, 1998). Snf1p also controls other transcription factors, such as Rgt1p, crucial for fine control of expression of the hexose transporters, Cat8p, required for gluconeogenesis, or Adr1p, important for ethanol utilization and fatty acid metabolism (Palomino et al., 2006; Hedges et al., 1995; Rande-Gil et al., 1997; Young et al., 2002). In addition, extracellular glucose concentrations are also sensed by the G-protein coupled receptor (GPCR) Gpr1p, which regulates Rgt1p and thus expression of hexose transporters via the cAMP/PKA pathway (Xue et al., 1998; Brown et al., 2014b).

In *C. albicans* the Snf3p/Rgt2p homologue Hgt4p is implicated in glucose sensing and regulation of the expression of at least six hexose transporter encoding genes and was found to be relevant for virulence (Brown et al., 2006). Snf1 has not been well characterized yet; it was initially described to be an essential enzyme, although more recently it has been shown that null mutants are viable, and it seems to be regulated by ATP levels rather than glucose availability (Thewes et al., 2007; Zhang et al., 2018; Mottola et al., 2020). One way in which Snf1p maintains ATP homeostasis is through regulation of carbon metabolism during normoxia, a function carried out by Snf5p during hypoxia (Burgain et al., 2019). Snf5p is critical for intestinal colonization in mice and virulence in *Galleria mellonella*. In *C. albicans* Mig1p, and its paralogue Mig2p, primarily act as inhibitors and play an important role in the regulation of genes involved in the import of carbohydrates and catabolic factors (Murad et al., 2001a; Lagree et al., 2020). Surprisingly Mig1p was dispensable for growth in a murine model of systemic candidiasis (Zaragoza et al., 2000). Tup1p co-represses a subset of Mig1p targets, in addition to regulating some genes independently of Mig1p, and contributes to pathogenicity (Ruben et al., 2020; Murad et al., 2001b).

In *C. neoformans*, the proteins responsible for glucose sensing have not been identified yet (Liu et al., 2013). In contrast, Snf1p has been characterized and linked to CCR and its relevance in virulence was demonstrated (Hu et al., 2008a; Yang et al., 2010). Mig1p regulates enzymes involved in synthesis of and energy release from alternative carbon sources (Caza et al., 2016). It also acts on genes involved in heme biosynthesis, and together with Tup1p it has been indicated to play a role in adaptation to iron limiting conditions (Lee et al., 2009). However, Mig1p was found to be expendable for virulence in a murine model of cryptococcosis (Caza et al., 2016).

In filamentous fungi, GPCR and the cAMP/PKA pathway have also been shown to mediate glucose sensing (Lafon et al., 2006). However, the presence of Snf3/Rgt2- type of sensors has not been shown to date, although in *A. nidulans* it was suggested that the transporter HxtB may be involved in glucose signalling (dos Reis et al., 2017). As in yeasts, SnfA controls nuclear/cytoplasm localization of CreA, but the role of this kinase is not well characterised in filamentous fungi yet (Brown et al., 2013; Ries et al., 2018). The role of the transcriptional factor CreA has mostly been studied in *A. nidulans*. In the presence of glucose CreA is translocated to the nucleus and represses genes encoding enzymes for the utilisation of alternative carbon sources (Kulmburg et al., 1993; Tamayo et al., 2008; Ries et al., 2016). In contrast to yeasts, the Tup1p homologue, RcoA, appears not play a direct role in CCR of filamentous fungi, although it affects chromatin structure and indirectly CreA binding to some promoters (García et al., 2008). Deletion of CreA is lethal in *A. nidulans* and other filamentous fungi such as *Fusarium oxysporum*, but not in *A. fumigatus* (Dowzer and Kelly, 1991; Jonkers and Rep, 2009; Beattie et al., 2017). In this pathogen, transcriptome data indicated that CreA is a critical regulator of carbon metabolism and cell energetics and that, unlike yeast Mig1, it both inhibits and activates gene expression. Inhibited pathways include gluconeogenesis and the transport and synthesis of alternative carbon sources such as carbohydrates and amino acids. Interestingly, it has been shown that CreA plays a role in regulating these genes during infection to ensure appropriate responses to changing nutrient availability during infection and is thus crucial for diseases progression in a murine model of invasive pulmonary aspergillosis (Beattie et al., 2017). Additionally, its deletion increases sensitivity to mitochondrial inhibitors and azoles (Furukawa et al., 2020; Beattie et al., 2017). Three additional proteins regulate CCR in filamentous fungi, a deubiquitination enzyme CreB, a WD-40 repeat protein CreC and an arrestin protein CreD. CreB and CreC act in complex to accomplish correct glucose repression, likely through deubiquitination of CreA, although there is still some controversy on the implication of ubiquitination in CreA regulation (Lockington and Kelly, 2002, 2001; Ries et al., 2016; Alam et al., 2016). CreD seems to oppose CreB-CreC action, by ubiquitinating CreA in conjunction with the ubiquitination ligase HulA (Boase and Kelly, 2004).

Uptake of carbon sources

Transport across the membrane is the first step in the metabolism of extracellular carbon sources. As a result, fungi possess numerous transporters and permeases which have evolved to facilitate this critical function. In this section we will focus on transporters of the preferred carbon source, sugars, while the mechanisms involved in transportation of secondary C-sources will be explored in the relevant sections of this chapter.

S. cerevisiae has approximately 20 hexose transporters which impact the pattern of sugar utilization as they vary in their affinity and specificity to particular monosaccharides including glucose, fructose and mannose (Wieczorke et al., 1999; Reifemberger et al., 1997; Guillaume et al., 2007). The induction of these genes is controlled by Snf3p and Rgt2p in response to source availability (Ozcan et al., 1996). In the absence of glucose, Rgt1p forms a complex with Mth1p, Std1p and Snf6p-Tup1p, repressing the expression of hexose transporter-encoding genes. In the presence of glucose, Rgt2p and Snf3p mediate phosphorylation, via casein kinase I (Yck1p/Yck2p), of Mth1p and Std1p, which leads to their degradation by the proteasome, and consequently Rgt1p dissociation from the promoter regions (Kim et al., 2013). Many of the yeast transporters have different affinities for multiple sugars and as such are able to sense sugar ratios which has positive implications for fitness (Escalante-Chong et al., 2015).

S. cerevisiae also has transport systems for the active uptake of disaccharides such as sucrose and maltose, with different affinities to ensure uptake of complex sugars in different conditions (Badotti et al., 2008; Henderson and Poolman, 2017). *C. albicans* has a similar system for the uptake of sugars, with at least 20 known glucose transporters (Fan et al., 2002). Similarly to in *S. cerevisiae*, the Snf3p/Rgt2p orthologue, Hgt4p, regulates the transcription of hexose transporters in response to carbon availability (Brown et al., 2006). This allows the fungus to exploit varying carbon sources encountered in disparate niches and to simultaneously assimilate preferred and alternative carbon sources (Sandai et al., 2012). The expression of numerous hexose transporters is upregulated in murine models of candidiasis showing that glucose sensing and/or transport is important for infection (Fanning et al., 2012; Cheng et al., 2013a; Xu et al., 2015). *C. neoformans* encodes over 50 hexose transporter homologues, however few have been characterized (Liu et al., 2013). Hxt1p is one high affinity glucose transporter that is highly expressed during the initial stages of pulmonary infection, suggesting glucose limitation is experienced by the fungus during the establishment of infection in this niche (Hu et al., 2008a). Hxs1p is an additional high affinity glucose transporter which is essential for full virulence in a murine inhalation model (Liu et al., 2013). In *C. neoformans* mannose is a relevant sugar, which is required in large quantities to maintain its polysaccharide capsule (Bose et al., 2003). Accordingly, it has been found to encode two GDP-mannose, a mannose donor, transporters which are differentially expressed in various environmental conditions and have different contributions to normal capsule formation (Cottrell et al., 2007).

A. nidulans has multiple energy dependent glucose transporters, which similarly to the situation in yeast, can transport multiple sugars with varying affinity (dos Reis et al., 2013; Forment et al., 2014, 2006; Wei et al., 2004; Colabardini et al., 2014). However, none were found to possess the cytosolic tail present in Snf3 and Rgt2 that are required for intracellular signalling (dos Reis et al., 2013). The signalling mechanisms remain uncharacterized, however transcription of the transporters is increased under glucose limiting conditions (dos Reis et al., 2013, 2017). In *Aspergillus niger* numerous putative sugar transporters, with varying substrate specificity, have been identified and shown to display differing expression profiles on various carbon sources (Mäkelä et al., 2018). In this species five transcription factors were found to regulate subsets of sugar transporters, some transporters were regulated by multiple transcription factors (Peng et al., 2018). This allows the fungus to finely tune the response to dynamic nutritional environments. In *A. fumigatus* large numbers of potential sugar transporters have been identified which are differentially induced on various carbon sources (de Gouvêa et al., 2018); however, glucose transporters and their regulation have not been investigated in detail in this species.

After acquisition of sugars, their phosphorylation is often the next metabolic step. *S. cerevisiae* encodes three glucose phosphorylation enzymes, Hxk1p, Hxk2p and Glk1p, which accept different sugars as substrates and phosphorylate these at different rates (Lobo and Maitra, 1977). The hexokinase Hxk2p is a critical glucose kinase that has both glycolytic action and a role in the nucleus as a transcription regulator (Randez-Gil et al., 1998). Transportation into the nucleus is partially determined by its phosphorylation status which is governed by Snf1p and the phosphatase Glc7p (Fernández-García et al., 2012). Research indicates that Hxk2p's conformation is determined directly by cytosolic glucose levels, so that at high glucose levels binding to Mig1p to form a stabilized repressor complex is promoted (Vega et al., 2016). *C. albicans* has four sugar kinases that play a role in glucose metabolism, Hxk1p, Hxk2p, Glk1p and Glk4p (Laurian et al., 2019). Hxk2p and both Glk glucokinases directly contribute to glucose phosphorylation and their expression is positively regulated by Hxk1p (Wijnants et al., 2020). The deletion of *HXK1* singly decreases biofilm formation, a virulence factor in *Candida*, whereas deletion of all four sugar kinases, or the combination of *HXK2*, *GLK1* and *GLK2*, attenuates virulence in a murine model of systemic candidiasis (Wijnants et al., 2020). In *C. neoformans*, a *HXK1* and *HXK2* double deletion strain is unable to utilize glucose and displays severely reduced virulence in a murine inhalation model (Price et al., 2011). In *A. fumigatus* sugar phosphorylation is dependent on a glucokinase, GlkA, and hexokinase, HxkA, which have different efficacies for activating various sugars (Fleck and Brock, 2010). Both enzymes are required for proper CCR and growth, deletion of *glkA* results in delayed germination, whereas *hxkA* has a stronger impact on mycelial growth (Fleck and Brock, 2010).

Nitrogen metabolism

Nitrogen is an essential nutrient that is required for most biosynthetic processes. To facilitate growth within the human body pathogenic fungi are able to utilize a wide variety of nitrogen sources. However, particular sources are favored as their efficient assimilation makes them energetically favorable (Tudzynski, 2014). Ammonia and asparagine are among these preferred nitrogen sources and are present in all major tissue locations (Marzluf, 1997; Lee et al., 2013b). Ammonia concentrations in the plasma of healthy individuals is limiting at approximately 20 μM , although it can be elevated by a range of health conditions including cystic fibrosis (Ucar et al., 2016). Some species, such as *A. fumigatus*, can produce ammonia from nitrate in the absence of a preferred nitrogen source (Zhou et al., 2002). Glutamine is another preferred source found in a more limited number of tissues, including the gut, kidney and blood where it is the most abundant free amino acid, at concentrations of $\sim 650 \mu\text{M}$ (Lee et al., 2013b; Blomstrand and Essén-Gustavsson, 2008; Mandal et al., 2012). An additional favored source, glutamate, is an important signalling molecule in various tissues throughout the human body (Bai and Zhou, 2017). Concentrations of the amino acid vary among tissue types, reaching around 100 μM in plasma and 6 μM in the cerebral spinal fluid (Madeira et al., 2018a, b). For many fungi the primary site of infection are the mucosal membranes of the gastrointestinal, ocular, respiratory, reproductive or urinary tracts. These epithelia secrete large quantities of mucin glycoproteins which likely act as alternative nitrogen and/or carbon sources (Linden et al., 2008). Similarly, upon invasion of underlying tissue their predominate source of nitrogen will likely be proteins, including collagen and elastin, peptides and amino acids (Farnell et al., 2012; Brandão et al., 2018).

In addition to the difference in nitrogen availability encountered between tissues the health status, antimicrobial exposure, activity level and diet of the host can cause rapid shifts (Blomstrand and Essén-Gustavsson, 2008; Schmidt et al., 2016; Gaston et al., 2002). To maximize growth, fungi are able to inhibit the use of alternative nitrogen sources under dynamic conditions when preferred sources are available, by a process termed nitrogen catabolite repression (NCR) (Wong et al., 2008). Indeed, the nitrogen sources utilized influences morphological transitions and the production of virulence factors by various pathogenic fungi (Lee et al., 2013b).

Regulation of nitrogen metabolism

When preferred nitrogen sources are limited GATA transcription factors regulate expression of many nitrogen catabolic enzymes (Marzluf, 1997). These regulators play a key role in the exploitation of a range of nitrogen sources in three major fungal pathogens: *A. fumigatus*, AreA, *C. albicans*, Gat1p and Gln3p, and *C. neoformans*, Gat1p (Liao et al., 2008; Lee et al., 2011; Hensel et al., 1998). They allow the utilization of alternative sources by activating the expression of proteins that facilitate their breakdown and uptake. NCR forms part of a very complex regulatory network that includes many enzymes, some of which play roles in processes beyond nitrogen utilization. Therefore, when specific enzymes are shown to be relevant for virulence, it is not always possible to establish a direct correlation with their role in nitrogen metabolism (Lee et al., 2011).

The critical role of NCR and AreA in determining nitrogen utilization has been most extensively studied in *A. nidulans*; in fact the latter was the first GATA transcription factor identified as coordinating nitrogen utilization and is highly conserved in *Aspergillus* species (Arst and Cove, 1973; Han et al., 2016). The level of AreA within the cell must be tightly controlled so the fungus maintains a hierarchy of utilization of preferred nitrogen sources (Morozov et al., 2001). One mechanism by which the levels of AreA are modulated involves the sensing of intracellular nitrogen availability: AreA mRNA is degraded when preferred nitrogen sources are abundant, this is primarily but not exclusively determined by glutamine levels (Morozov et al., 2001). In addition, a co-repressor, NmrA, competes with DNA to bind AreA in the presence of preferred nitrogen sources, therefore reducing expression of nitrogen catabolic enzymes that are upregulated by AreA (Kotaka et al., 2008; Morozov et al., 2001). Expression of NmrA is positively regulated by the transcription factor MeaB during nitrogen sufficiency (Wong et al., 2007). When preferred nitrogen sources are limiting three *A. nidulans* proteases cleave NmrA, thereby removing its inhibition of the utilization of alternative nitrogen sources (Zhao et al., 2010). The transcriptional function of AreA requires nuclear localization, which is facilitated by its unusually high number of nuclear localization signals (Hunter et al., 2014). Once in the nucleus, AreA can interact with its co-activator TamA to initiate the expression of nitrogen catabolic enzymes (Small et al., 2001). An additional GATA transcription factor, AreB, is involved in nitrogen and also carbon catabolite repression in *A. nidulans*, seemingly via regulation of key factors as AreA, TamA or CreA (Chudzicka-Ormaniec et al., 2019). AreA is not necessary for *A. fumigatus* growth on ammonium or glutamine, although growth is reduced compared to wildtype at low concentrations (Hensel et al., 1998). It is essential for growth on many amino acids, including glutamate and asparagine, and when using collagen as the primary source of nitrogen when a preferred carbon source is available (Hensel et al., 1998). In a murine model of invasive pulmonary aspergillosis loss of AreA in *A. fumigatus* resulted in a minor delay and slight reduction of mortality (Hensel et al., 1998). This delay in virulence might be explained by an interruption in germination, as AreA is upregulated ~9 fold during the initiation of germination in wildtype conidia (Lamarre et al., 2008).

C. albicans processes two important GATA transcription factors, Gln3 and Gat1, with partially redundant functions. Their deletion allows growth on a wider range of nitrogen sources than upon deletion of AreA in *A. fumigatus* (Liao et al., 2008; Limjindaporn et al., 2003). Single and double mutants are able to utilize ammonium as the sole nitrogen source, however Gln3p is necessary for normal filamentous growth in nitrogen limiting conditions (Dabas and Morschhäuser, 2007). Both Gat1p and Gln3p contribute significantly to the virulence of *C. albicans* in murine models of disseminated candidiasis (Limjindaporn et al., 2003; Liao et al., 2008). Similarly to the theory proposed for *A. fumigatus*, this might be due to the misregulation of nitrogen utilization but also to impaired filamentation during infection. In *C. neoformans* Gat1p is responsible for the utilization of many nitrogen sources, including ammonium, and has a complex regulatory role during infection as it contributes to a wide variety of pathways (Cui et al., 2019; Lee et al., 2013b; Kmetzsch et al., 2011); its deletion, however, did not compromise virulence in a mouse model of pulmonary cryptococcosis (Kmetzsch et al., 2011). GATA repressors are not well characterized however, the genomes of *C. albicans* and *C. neoformans* do not appear to encode homologues of NmrA (Ries et al., 2018). One putative GATA repressor, Gzf3p, has been identified in *C. albicans*, but its function has not to date been thoroughly investigated (Holland et al., 2014). However, the homologue of Gzf3p in *Candida parapsilosis* has been shown to mediate NCR (Turner et al., 2018). These three species highlight that within NCR systems utilized to exploit appropriate nitrogen sources, the mechanisms involved can vary significantly and that there are many opportunities to advance the field's knowledge of the role of nitrogen metabolism during fungal infection. In line with this, the importance of investigating NCR in *Paracoccidioides* pathogens has recently been highlighted (Milhomem Cruz-Leite et al., 2020).

Uptake of nitrogen sources

The enzymes that sense and transport extracellular nitrogen containing compounds are central to the ability of fungi to correctly utilize available nitrogen sources, and are therefore a potential source of promising antifungal targets. Fungi express a broad spectrum of transporters and G-protein-coupled receptors to allow the uptake of preferred and alternative nutrient sources (Diallinas, 2017; Rutherford et al., 2019), several of which have been implicated in virulence (Brown et al., 2018).

Fungal ammonium permeases are critical as they allow the detection and uptake of preferred sources, even when present at limited concentrations (Rutherford et al., 2008). *C. albicans* has two ammonium permeases, Mep1p and Mep2p, that allow growth

even at low levels of ammonium (Biswas and Morschhauser, 2005). At high concentrations the transporters are not required for growth, presumably as ammonium uptake is possible through nonspecific uptake or simple diffusion (Biswas and Morschhauser, 2005). Mep2p has an additional role in pseudohyphal growth induction when it is not utilized for ammonia uptake, thereby using low ammonium conditions as an inducer of morphogenesis (Biswas and Morschhauser, 2005). Expression of *MEP2* is induced under limiting conditions by Gat1p and Gln3p (Dabas and Morschhäuser, 2007). *C. neoformans* has two ammonium transporters, Amt1p and Amt2p, which are also essential for growth in ammonium limiting conditions and the formation of pseudohyphae, but are dispensable for virulence (Lee et al., 2012b; Rutherford et al., 2008). A homologous putative ammonium transporter, MeaA, has been identified but not characterized in *A. fumigatus* (Escobar et al., 2018).

The ability of fungal pathogens to breakdown complex polypeptides and to assimilate the breakdown products from the extracellular space is key to survival within many host niches, particularly in environments such as the lung where proteins dominate as a nitrogen source (Farnell et al., 2012). *A. fumigatus* secretes an impressive variety of secreted proteases, with the particular combination depending on nutrient availability (Farnell et al., 2012). However, elimination of the transcription factors PrtT and XprG, positive regulators of the expression of secreted proteases, alone or in combination did not reduce *A. fumigatus* virulence in models of systemic and pulmonary invasive infection (Sharon et al., 2009; Bergmann et al., 2009; Shemesh et al., 2017). A high degree of redundancy within secreted proteolytic activities may explain why none have been found to be essential for growth within host tissues (Ries et al., 2018). Therefore, the relevance of proteases for *A. fumigatus* virulence still needs to be clarified. Nevertheless, fungal secreted proteases are important allergens, which has been proposed to be caused by their activity to cleave fibrinogen and activate TLR4 signalling (Millien et al., 2013). For instance, the serine protease Alp1/Aspf13 has been shown to be relevant in asthma where it causes degradation of the extracellular matrix within the bronchioles of patients (Druey et al., 2020).

C. albicans produces 10 secreted aspartic proteases (SAP) which are differentially secreted as infection progresses and are implicated in epithelial damage (Naglik et al., 2008). SAPs can cleave a variety of human proteins that could be used to provide nitrogen and six have been shown to contribute to virulence of *C. albicans* in rodent infection models (Cassone et al., 2016; Naglik et al., 2003; Hube et al., 1997; Sanglard et al., 1997).

In *C. neoformans* the urease Ure1p is an important virulence factor in murine cryptococcosis models of intravenous and inhalation infections (Cox et al., 2000). The enzyme is not required for growth in the brain but plays a role in dissemination and central nervous system invasion (Olszewski et al., 2004). Similarly, deletion of the urease and ureidoglycolate hydrolase genes in *Coccidioides posadasii* significantly reduced virulence in a murine model of infection (Wise et al., 2013). Serine proteases were also implicated as playing a role in the permeabilization of the blood brain barrier (Xu et al., 2014a). The *C. neoformans* genome encodes 8 putative global amino acid permeases, two of which are essential for virulence in an inhalation model of murine cryptococcosis (Martho et al., 2016).

Sulfur metabolism

Sulfur is an essential nutrient involved in a multitude of crucial metabolic processes in fungi. For instance, it is constituent of the proteogenic amino acids cysteine (Cys) and methionine (Met). Sulfur is very relevant for oxidative stress defense, as the thiol group in the redox-active molecules glutathione, thioredoxin, peroxiredoxin and ergothioneine is fundamental for their activity (Ulrich and Jakob, 2019). Sulfur is also fundamental for methylation reactions, as it is an integral constituent of the major cellular methyl donor S-adenosylmethionine (SAM), the synthesis of which is essential for fungal viability (Chiang et al., 1996; Gerke et al., 2012). Sulfur is also crucial for enzymatic functions, as it is integral component of several major co-factors as Fe-S clusters (which are also fundamental for iron sensing), vitamins (biotin, thiamine, pantothenic acid) and co-enzyme-A (Misslinger et al., 2018; Sprenger et al., 2020; Dietl et al., 2018; Nakamura et al., 2012).

Regulation of sulfur metabolism

The regulation of sulfur metabolism in pathogenic fungi has been mostly investigated in filamentous fungi, where it is tightly regulated by catabolite repression (Marzluf, 1993). The Cys3/MetR bZIP transcriptional factor activates its own expression and that of genes required to acquire and utilize sulfur sources upon S-starvation (Paietta et al., 1987; Petra et al., 1992; Natorff et al., 2003). This activator is crucial for *A. fumigatus* and important for *C. neoformans* virulence and is important for the regulation of sulfur assimilation in the dimorphic switch of *Paracoccidioides brasiliensis* (Amich et al., 2013; de Melo et al., 2019; Ferreira et al., 2006). In *A. nidulans*, an additional transcriptional factor, MetZ, has been described, seemingly involved in the regulation of sulfur metabolism (Pilsyk et al., 2015). In conditions of sufficient sulfur the so-called sulfur controller (*scon*) genes negatively impact Cys3, most likely through its proteolytic degradation (Natorff et al., 1993; Kumar and Paietta, 1998; Paietta, 1990; Peterson et al., 2014). Regulation of sulfur metabolism has also been extensively studied in *Saccharomyces cerevisiae*, where a heteromeric complex of three proteins (Met4p-Met28p-Cbf1p) is responsible for transcriptional regulation (Kuras and Thomas, 1995; Thomas et al., 1992; Kuras et al., 1996). Sulfur regulation has not been investigated in detail in *Candida* species, but it seems to resemble the situation in *S. cerevisiae* (Hébert et al., 2011).

Uptake of sulfur sources

Fungi can assimilate sulfur from inorganic and organic sources. Assimilation of sulfate has been well characterized in yeasts and filamentous fungi, where it is first transported into the cell by a sulfate permease and subsequently reduced to adenosine

5'-phosphosulfate (APS) by an ATP sulfurylase. APS is then phosphorylated by an APS kinase to form 3'-phosphoadenosine 5'-phosphosulfate (PAPS) followed by sulfite release from PAPS by action of a PAPS reductase. Sulfite is reduced to sulfide by a sulfite reductase and can then be incorporated into cysteine via O-acetylserine through a process catalysed by a cysteine synthase or into homocysteine via O-acetylhomoserine through a process catalyzed by a homocysteine synthase (Marzluf, 1997). Homocysteine can be methylated to form methionine, and cysteine and methionine can be interconverted within the trans-sulfuration pathway. Fungi can assimilate sulfur from chemically diverse organic sources, as reviewed in (Linder, 2018). Many of these routes converge in the sulfate assimilation pathway, as the rhodanese dependent processing of thiosulfate, the arylsulfatase dependent assimilation of sulfate esters or the assimilation of volatile sulfur compounds (Chen et al., 2018; Linder, 2018; Scott et al., 2019). However, an *A. fumigatus* sulfite reductase mutant was fully virulent, suggesting that the assimilation of inorganic and complex organic S-sources is not relevant in the mammalian tissues (Amich et al., 2016). Nevertheless, high levels of sulfate esters can be found on the airway and intestinal epithelial surfaces (e.g. sulfated mucins) and of sulfamates in the extracellular matrix (e.g. heparan sulfate), so more studies are needed to definitely exclude these compounds as S-sources. Most likely fungal pathogens obtain sulfur from the S-containing amino acids cysteine and methionine and their derivatives (SAM, glutathione, etc...), based on uptake by amino acid permeases and oligopeptide transporters (Amich et al., 2016). This idea is also supported by the impossibility of several dimorphic fungi to assimilate inorganic sulfur source in the pathogenic yeast form (Medoff et al., 1987; Paris et al., 1985; Boguslawski and Stetler, 1979). However, even if there are specific transporters described, as Mup permeases for methionine uptake, the presence of general amino acid permeases makes it difficult to specifically prevent uptake of the S-containing amino acids to validate this hypothesis (Isnard et al., 1996; Garbe and Vylkova, 2019; Martho et al., 2016).

Micronutrients

Micronutrients or microelements are those that fungi require in trace amounts and are usually cofactors and coordinators of the molecules of life.

Iron

The biological functions of iron are based on its ability to cycle between two oxidation states: ferrous (Fe^{2+}) and ferric (Fe^{3+}). The corresponding redox potential makes it an ideal catalyst for a multitude of cellular and metabolic processes, including respiration and DNA replication. In humans most of the iron in circulation is complexed with heme, bound by hemoglobin within red blood cells. In plasma, iron is bound to transferrin, which is used to safely distribute this element to cells. In cells, excess of iron (not incorporated in iron-sulfur clusters or redox co-factors) is stored in ferritin. From a host side of view, the availability of iron and other trace elements is actively reduced during infection as a strategy to limit pathogen growth. This process has been termed nutritional immunity and is paramount for antimicrobial defense (Hood and Skaar, 2012). In order to scavenge extracellular iron, neutrophils secrete lactoferrin, an iron-binding glycoprotein (Lönnerdal and Iyer, 1995; Zarembek et al., 2007). Furthermore, in response to inflammatory stimuli hepatocytes secrete hepcidin, a hormone that triggers the internalization and degradation of the cellular iron exporter ferroportin, therefore reducing iron export from macrophages and enterocytes and decreasing the levels of extracellular iron (Nemeth and Ganz, 2009).

Fungi have evolved four different strategies for iron uptake. Fungal pathogens have the genes required to deploy several but not all of the below strategies. The relative relevance of each strategy (set of genes) for fungal virulence mostly depends on the source of iron at the site of infection.

One strategy is low affinity iron uptake, which is based on permeases (Fet4p, Smf1p) that are not specific for ferrous iron, but also can transport other metals (Kaplan and Kaplan, 2009). Although this system is present in many pathogenic fungal species, it does not seem to be important for virulence (Jung et al., 2008). Nevertheless, it appears to be relevant for iron uptake under hypoxic conditions, a condition that is known to impact iron homeostasis, and therefore a role of low-affinity iron uptake for fungal virulence cannot be completely excluded yet (Jensen and Culotta, 2002; Chung et al., 2012; Blatzer et al., 2011).

Another strategy for iron uptake is reductive iron assimilation, which involves two sequential steps: first a reduction of ferric iron to soluble ferrous iron by membrane-located ferric reductases, encoded by the *FRE* genes, to be followed by subsequent re-oxidation to the ferric form by a high-affinity heterodimeric transport complex consisting of the multicopper ferroxidase Fet3 and the permease Ftr1. *FRE* reductases are integral membrane proteins that require heme, FAD and or NAD(P)H (Philpott, 2006). Most pathogenic fungi encode several ferric reductases, such as 18 in *C. albicans*, 15 in *A. fumigatus* or 8 in *C. neoformans*, but likely not all of them exert a ferric reductase activity (Jeeves et al., 2011; Saikia et al., 2014; Fourie et al., 2018). Ferrous iron needs to be re-oxidized in a reaction that is copper dependent, and copper ions are inserted into Fet3 action of the chaperone Atx1 and the pump Ccc2 (Lin et al., 1997; Yuan et al., 1995). The transport of ferric iron involves a classic metabolite channelling mechanism where amino acid residues in both Fet3 and Ftr1 interact with each other to drive the iron into the cell (Kwok et al., 2006). Reductive iron assimilation has been shown to be important for virulence of various fungal pathogens, as *C. albicans* (where is also required for iron acquisition from transferrin and ferritin), *C. neoformans*, *C. glabrata* (although the latter does not contain ferric reductases), *Rhizopus oryzae*, *Mucor circinelloides* (Navarro-Mendoza et al., 2018; Ibrahim et al., 2010; Gerwien et al., 2017; Srivastava et al., 2014; Xu et al., 2014b; Cheng et al., 2013b; Knight et al., 2005; Ramanan and Wang, 2000; Almeida et al., 2008; Saikia et al., 2014; Jung et al., 2008, 2009). *Paracoccidioides* spp., have a non-traditional reductive iron assimilation, involving iron reduction and

zinc-regulated transporter homologs, which has been suggested to be important for persistence in macrophages (Camacho and Niño-Vega, 2017; Bailão et al., 2015).

An alternative mechanism is the acquisition of iron from heme, most of which is bound to hemoglobin, which contains about 70% of the total body iron in humans. Some fungi have evolved a distinct pathway to scavenge iron from heme and hemoglobin. This pathway can be divided in three steps. Firstly proteins containing a domain exclusively found in fungi, named Common in Fungal Extracellular Membrane (CFEM), extract heme from the host hemoglobin and mediate its delivery to the fungal cell (Weissman and Kornitzer, 2004). At least three of the six CFEM proteins present in *C. albicans* genome seem to form a transfer cascade for heme, from extracellular secreted Csa2p to the cell wall anchored Rbt5p and then to Pga7p on the plasma membrane (Kuznets et al., 2014; Nasser et al., 2016). Subsequently, heme is delivered through the endocytic system to the vacuole compartment via action of several ESCRT (endosomal sorting complex required for transport) proteins and a type I myosin (Myo5p) (Weissman et al., 2008). Finally, the oxygenase Hmx1p metabolizes heme and has been described to be required for its utilization, although other studies suggested that alternative heme-degrading enzymes may exist in the vacuole (Pendrak et al., 2004; Santos et al., 2003; Roy and Kornitzer, 2019). Heme uptake seems to contribute to *C. albicans* virulence (Kuznets et al., 2014). Other *Candida* species can also utilize heme (Pinsky et al., 2020). In *Cryptococcus neoformans* it is still unclear whether CFEM proteins are involved in heme binding and internalization; a secreted mannoprotein (Cig1p) is likely able to perform this function and was reported to contribute to *C. neoformans* virulence (Bairwa et al., 2019). For heme endocytic delivery to the vacuole in *C. neoformans* has been shown that in addition to ESCRT proteins, several components of the clathrin mediated endocytosis are required for hemoglobin utilization, elaboration of virulence factor and pathogenesis (Hu et al., 2015; Bairwa et al., 2019). Hemoglobin uptake also seems to be required for *Paracoccidioides* ssp. virulence (Bailão et al., 2014).

A relevant strategy that fungi use to acquire iron is the utilization of siderophores, heterogeneous small molecules secreted by bacteria and fungi, which bind extracellular ferric iron with extremely high affinity. Many fungi produce hydroxamate-type siderophores to solubilize and take up iron (Haas et al., 2008). Siderophores are important for the virulence of fungal pathogens that produce them, for instance *Histoplasma* and *A. fumigatus* and its synthesis has been extensively studied in the latter (Haas, 2014; Schrettl et al., 2004; Hwang et al., 2008). *A. fumigatus* produces four siderophores: two extracellular fusarinine-type siderophores, fusarinine-C and triacetylfusarinine-C for iron uptake, and two intracellular ferrichrome-type siderophores, ferricrocin for iron distribution and storage in hyphae and hydroxyferricrocin for storage of iron in spores (Schrettl et al., 2007). The biosynthetic pathway starts with the N^5 -hydroxylation of L-ornithine catalysed by the L-ornithine- N^5 -monooxygenase SidA (Schrettl et al., 2004). Subsequently, the pathway splits in two branches to form extracellular (by action of SidF, SidD and SidG) and intracellular (by action of SidL, SidC) siderophores (Haas, 2014). Siderophore-iron complex uptake is mediated by the siderophore-iron transporters (SITs), which belong to the major facilitator protein superfamily (Yun et al., 2000a, b). SIT transporters are present in all fungal species, even in those not producing siderophores. Species such as *Candida* spp. and *C. neoformans* can exploit xenosiderophores (i.e. siderophores produced by other bacteria or fungi), which probably confers an advantage in competing microbial interactions, but is not required for virulence (Hu et al., 2002; Tangen et al., 2007). Finally, iron is released from the internalized siderophores by action of specific esterases to incorporate it in the fungal metabolism or transfer it to intracellular siderophores for storage (Kragl et al., 2007; Ecker et al., 2018).

Transcriptional regulation of iron homeostasis is conserved in virtually all pathogenic fungi, with the prominent exception of *C. glabrata* (Gerwien et al., 2016). This homeostatic system comprises two transcriptional factors, a GATA transcription factor that downregulates iron acquisition (called Sfu1, Cir1, SreA) and a CCAAT-binding complex that upregulates iron acquisition and downregulates iron consumption pathways (Hap43, HapX) (Chen et al., 2011; Lan et al., 2004; Hwang et al., 2012; Hsu et al., 2011; Jung et al., 2010; Schrettl et al., 2010). These factors are interconnected in a negative feed-back loop: Sfu1/SreA represses expression of *hap43/hapX* during iron sufficiency, while Hap43/HapX represses *sfu1/sreA* during iron starvation (Singh et al., 2011; Chen et al., 2011; Haas, 2014). *A. fumigatus* HapX has been shown to be important not only under iron starvation, but also to activate iron detoxification mechanisms at high iron concentrations, a double function that appears to be conserved in other fungal pathogens (Gsaller et al., 2014). Both Sfu1/SreA and Hap43/HapX function seems to be regulated by direct iron binding, which apparently block HapX and activates SreA function (Hortschansky et al., 2007; Haas et al., 1999). In addition, the monothiol glutaredoxin (Grx4/GrxD) is essential for sensing the availability of iron and to control the activity of the transcriptional factors (Attarian et al., 2018; Misslinger et al., 2019). Given the lower availability of iron in human tissues, it is not surprising that Hap43/HapX are essential for virulence in all fungal pathogens studied so far (Schrettl et al., 2010; Hsu et al., 2011). In *C. albicans* Sfu1 is required for persistence in the iron-replete gut, illustrating the importance of adaptation to different iron availability conditions (Chen et al., 2011). Indeed, possibly due to this two lifestyles of *C. albicans* (as a commensal and as a pathogen), this species has incorporated a third regulator into the system (Sef1), to serve as an activator of Hap43 expression and that is required for full virulence (Chen and Noble, 2012).

Given the importance of iron homeostasis, it is not surprising that its regulation is tightly linked to the homeostasis of other elements (as copper, zinc or sulfur) and to the adaptation to particular conditions that can affect its availability or its cellular need (Hsu et al., 2011; Vicentefranqueira et al., 2019; Amich et al., 2013; Baek et al., 2008; Eisendle et al., 2004; Chung et al., 2012).

Zinc

Zinc is an essential metal crucial for many cellular functions and an indispensable micronutrient for all living organisms. Approximately 9% of all eukaryotic, including fungal, proteins specifically bind zinc (Andreini et al., 2009). This metal is co-factor of more than 300 enzymes and is the only metal present in all six types of enzymes (according to the functional

classification of the International Union of Biochemists) (Vallee and Galdes, 1984; Auld, 2001). Among its many functions, zinc is particularly important in DNA replication and transcription, as it is required for the activity of all DNA and RNA polymerases and a significant number of transcription factors contain zinc-finger domains (Wu and Wu, 1987; Andreini et al., 2006).

Acquisition of zinc is therefore essential for fungal viability and virulence. The concentration of free zinc in tissues and cells is however very low, as it is predominantly bound to proteins (Tapiero and Tew, 2003; Maret, 2015). Furthermore, similarly to iron, upon infection the host nutritional immunity can further reduce the availability of zinc through the activity of transporters or the expression of zinc-binding proteins, such as calprotectin (a neutrophil-produced member of the S100 family of metal-binding proteins) (Corbin et al., 2008; Urban et al., 2009). In addition, macrophages can intoxicate fungi inside lysosomes with zinc (Sacks et al., 2018). Accordingly, fungi contain specialized and tightly regulated systems for zinc uptake and homeostasis, which have been proven to be required for virulence in all the species studied to date (Wilson, 2015).

As for other metals, zinc homeostasis must be finely regulated to ensure uptake in restrictive conditions and prevent toxic effects. In fungi, the zinc responsive activator protein Zap1 is the major transcriptional factor regulating zinc homeostasis (Zhao and Eide, 1997). Under zinc limiting conditions, Zap1 (also known as Csr1 in *C. albicans* and ZafA in *A. fumigatus*) upregulates its own transcription, as well as of zinc importers (ZIP, Zrt-, Irt like Proteins) and cytosolic exporters (CDF cation diffusion facilitator or ZnT) (Kim et al., 2008b; Moreno et al., 2007; Gaither and Eide, 2001). The relevance of zinc importers for fungal virulence has been shown in all species studied (Amich et al., 2014; Crawford et al., 2018; Do et al., 2016; Schneider et al., 2015; Dade et al., 2016). In addition, some species as *C. albicans* and *A. fumigatus* secrete a zinc-binding protein ("zincophore") that can sequester the metal from host cells and facilitate its uptake (Cititolo et al., 2012; Amich et al., 2009; Wilson, 2015). Upregulation of ZnT transporters ensures prevention of toxic effects, and has been also shown to be important for fungal virulence (Crawford et al., 2018). Zap1 has also been implicated in the regulation of other virulence factors in some species, such as capsule and melanin formation in *C. neoformans*, *C. albicans* morphogenesis, biofilm formation and adhesion, or amino acid and gliotoxin biosynthesis in *A. fumigatus* (Liu et al., 2008; Jung et al., 2015; Kim et al., 2008b; Nobile et al., 2009; Finkel et al., 2012; Vicente-franqueira et al., 2018). Besides, in most fungal pathogens zinc transporters are co-regulated by the pH master regulator PacC/Rim101 and the activity of transporters is pH optimised, which is likely due to the lower solubility of Zn in alkaline pH (Wilson, 2015; Bensen et al., 2004; Amich et al., 2009, 2014; Crawford et al., 2018).

Copper

Copper is essential for eukaryotic life. The ability of copper to cycle between oxidized (Cu^{2+}) and reduced (Cu^+) states underlies its function as cofactor for many enzymes to catalyze biochemical processes as aerobic respiration (cytochrome-c oxidase), superoxide detoxification (superoxide dismutase), iron acquisition or pigmentation (tyrosinase) (Cox et al., 2003; Askwith et al., 1994; Gruhn and Miller, 1991). However, copper also rapidly becomes toxic at increased levels, as it can inactivate other metalloenzymes, inappropriately engage with intracellular metallophilic ligands and generate reactive oxygen species through Fenton-like chemistry. Therefore, copper homeostasis must be finely tuned to maintain its levels within homeostatic ranges. In fact, host nutritional immunity appears to utilize both copper sequestration and poisoning to fight fungal (and other) infections (Besold et al., 2016).

Upon copper limitation, a transcriptional factor called Mac1 in *A. fumigatus* and *C. albicans* and Cuf1 in *C. neoformans* activates uptake, which is based on membrane metalloredutases (FRE), that reduce Cu^{2+} to Cu^+ , and subsequent import via high-affinity Cu^+ importers, Ctr1 in *C. albicans*, Ctr1 and Ctr4 in *C. neoformans* and CtrC and CtrA2 in *A. fumigatus* (Park et al., 2017, 2014; Kusuya et al., 2017; Marvin et al., 2004, 2003; Waterman et al., 2007; Woodacre et al., 2008; Ding et al., 2011). Copper is then bound by chaperones that direct copper to the desired location: Atx1 to Ccc2 Cu-transporting ATPases of the Golgi membrane, Ccs1 to the Cu/Zn-superoxide dismutases (SODs) and Cox17 for transporting copper into mitochondria for the assembly of cytochrome c oxidase (Lin and Culotta, 1995; Lin et al., 1997; Culotta et al., 1997; Gleason et al., 2014; Boyd et al., 2018; Horng et al., 2004; Glerum et al., 1996; Punter and Glerum, 2003).

High intracellular copper levels are sensed by the same factor in *C. neoformans* (Cuf1), but a different factor in other species, named Cup2 in *C. albicans* and AceA in *Aspergillus* (Ding et al., 2011, 2013; Schwartz et al., 2013; Antsotegi-Uskola et al., 2017; Wiemann et al., 2017). These factors activate different mechanisms to prevent and counteract copper toxicity, as P1-type ATPase copper exporter, copper metallothioneins, accumulation in vacuoles and Fe-S biogenesis (Riggle and Kumamoto, 2000; Weissman et al., 2000; Wiemann et al., 2017; Oh et al., 1999; Ding et al., 2011; Rees and Thiele, 2007; Garcia-Santamarina et al., 2017).

As mentioned above, fungi may encounter copper limiting and toxic niches during infection, which implies that both Cu^+ acquisition and detoxification systems are likely relevant for fungal virulence. For instance, *C. neoformans* seems to face copper limitation in the brain and poisoning in the lung (Waterman et al., 2007; Ding et al., 2013). Copper detoxification is also important for *A. fumigatus* and *A. flavus* virulence, while the role of copper uptake is somewhat controversial as some studies reported its relevance for virulence, other reported no effect (Wiemann et al., 2017; Yang et al., 2018; Park et al., 2018; Cai et al., 2017). Similarly, studies in *C. albicans* have shown that a dynamic response is required to counteract both host-imposed limitation and poisoning (Besold et al., 2018).

Other metals

Many elements are required in trace amounts for the correct functioning of fungal cells. Here we discuss some of the most important elements which have been studied and are related with fungal virulence.

Calcium is a paramount signalling molecule in eukaryotes. In fungi it is essential for many processes such as growth and development, reproduction, stress adaptation and virulence. Calcium signalling is initiated by a sharp rise in cytosolic Ca^{2+} , which binds and changes conformation of Ca^{2+} -binding proteins, followed by a fast decrease in its concentration. These changes in intracellular calcium concentration are exerted by six major types of transporters that uptake Ca^{2+} from the extracellular space and mobilize or store it in organelles: high-affinity calcium system (HACS), low-affinity calcium system (LACS), Ca^{2+} pumps, $\text{Ca}^{2+}/\text{H}^{+}$ exchangers, TRP-like Ca^{2+} channels, and mitochondrial Ca^{2+} uniporters (MCU) (Lange and Peiter, 2020; Tisi et al., 2016). Changes in intracellular Ca^{2+} concentration are detected by sensors containing EF-hand motifs, as calmodulin or Neuronal calcium sensor-1 (Ncs-1, also known as Frq1 in *S. cerevisiae*), which activate specific downstream signalling cascades (Davis et al., 1986; Hendricks et al., 1999). One of the better characterized downstream pathways involve calcineurin and the transcription factor calcineurin-responsive zinc finger 1 (Crz-1), which are important in stress responses, morphogenesis and pathogenesis (Agranoff et al., 2005; Juvvadi et al., 2014; Tisi et al., 2016).

Manganese is required for polymerases, Golgi sugar transferases and Mn-SODs (Reddi et al., 2009a). Mn is taken up from the environment by transporters of the Nramp family, Smf1 and Smf2 (Portnoy et al., 2000; Agranoff et al., 2005). These transporters are constitutively transcribed and are mainly regulated post-translationally, targeted for vacuolar degradation when the intracellular content is sufficient (Reddi et al., 2009b). It is currently unknown if Mn^{2+} can be mobilized from the vacuole to respond to starvation. The host defense protein calprotectin can chelate Mn^{2+} to limit its access to pathogens, which has been shown to reduce *A. fumigatus* growth (Amich et al., 2014; Clark et al., 2016).

Magnesium is a critical cofactor of many enzymes and participates in essential processes as oxidative phosphorylation, nucleic acid synthesis and glycolysis. In *S. cerevisiae* several Mg^{2+} transporters have been described: two membrane importers (Alr1 and Alr2), a vacuolar transporter (Mnr2), and three mitochondrial transporters, two importers (Lpe10 and Mrs2) and one exporter (Mme1) (da Costa et al., 2007; Pisat et al., 2009; Cui et al., 2015). Mg^{2+} has been shown to modulate *C. neoformans* virulence factors, particularly capsule formation, and *C. albicans* virulence traits (Suo et al., 2018; Hans et al., 2019).

Nickel is a cofactor of urease in some fungal species, which is an important virulence factor for some pathogens as *C. neoformans* and *C. posadasii* (Singh et al., 2013; Fu et al., 2018; Olszewski et al., 2004; Wise et al., 2013). Although not much is known about nickel homeostasis, a Ni-permease has been described in *S. pombe* and a vacuolar storage detoxification response in *S. cerevisiae* (Hinnebusch, 1984; Eitinger et al., 2000), suggesting that a complete acquisition and homeostatic system must exist in fungi.

Metabolism of the four molecules of life

The four molecules of life (amino acids, lipids, nucleotides and sugars) are all vital for all organisms. They are the building blocks of biological macromolecules and their metabolism is at the core of primary metabolism. A deep understanding of fungal primary metabolism and its exploitation with modelling studies (bioinformatics and structural) has the potential to revolutionize the identification of valuable molecular targets (against which novel antifungal compounds can be developed) (Bencurova et al., 2018).

Amino acids

Amino acids are the crucial building blocks of all proteins. Unlike humans, pathogenic fungi are capable of biosynthesizing all 20 proteinogenic amino acids, however their uptake is energetically more favorable (Jastrzębowska and Gabriel, 2015). In host niches amino acids may serve as carbon and nitrogen sources such as in plasma, where free amino acid concentrations reach around 3.4 mM depending on diet and other factors, or in the lungs where concentrations can rise in response to inflammation (Blomstrand and Essén-Gustavsson, 2008; Hu et al., 2008b). Indeed, they are found in relatively large quantities in all tissues, contained within host proteins and peptides (Brosnan, 2003). To exploit these nutritional sources, pathogenic fungi possess mechanisms which allow the breakdown of exogenous proteins and the efficient assimilation of amino acids (Pérez et al., 2013; Farnell et al., 2012). Crucially, many of the enzymes involved in sensing, uptake and metabolism of amino acids are essential for fungal viability and virulence but are absent in humans, making them attractive targets for antifungal development (Amich and Bignell, 2016; Schobel et al., 2010; Pascon et al., 2004).

To ensure that preferred nitrogen sources, such as glutamine and glutamate, are utilized when available, fungi use a system of nitrogen catabolite repression. These responses are mediated by the upregulation of GATA transcription factors in nitrogen limiting conditions, allowing the uptake of alternative sources such as proline and arginine (Lee et al., 2013a; Coffman et al., 1995). Central to the ability of pathogenic fungi to respond to nutrient availability appropriately is the capacity to sense and differentiate between different nutrient concentrations (Crespo et al., 2002). The target of rapamycin (TOR) pathway is conserved as the main sensor of nutrient state in eukaryotes and plays an important role in mediating the response to different nutritional conditions, including alteration of amino acid transport and metabolism (Hardwick et al., 1999; Beck and Hall, 1999; Cardenas et al., 1999; Peng et al., 2002; Kim et al., 2008a; De Virgilio and Loewith, 2006). It is activated by amino-acid derived signals, including glutamine, and able to differentiate between nutrient availability conditions so the appropriate response is induced (Crespo et al., 2002; Baldin et al., 2015; Bastidas et al., 2009). In *A. fumigatus*, *C. albicans* and *C. neoformans*, Tor protein kinases are essential for viability and control a range of important metabolic and morphogenic features which contribute to pathogenicity (Bastidas et al., 2009; Martins et al., 2008; Cruz et al., 1999; Martho et al., 2016; So et al., 2019; Baldin et al., 2015; Böttcher et al., 2016). Unsurprisingly, interruption of downstream Tor signalling pathways results in attenuated virulence in murine models of invasive pulmonary aspergillosis, disseminated candidiasis and cryptococcosis (Han et al., 2019; Lee et al., 2004, 2012a; Rohde et al., 2004; Bastidas et al., 2009; de Castro et al., 2016; Bom et al., 2015).

An additional global regulator of metabolic and morphogenic responses to amino acid availability in fungi is the cross-pathway control (CPC) response or general amino acid control (GAAC), as it is called in filamentous fungi or yeasts, respectively (Carsiotis et al., 1974; Hinnebusch, 1984). Utilizing these systems fungi respond to limiting concentrations of a single amino acid by activating transcription of numerous amino acid biosynthetic genes (Tripathi et al., 2002; Lavoie et al., 2009; Lee et al., 2018). In *A. fumigatus*, intracellular amino acid starvation is sensed by a highly conserved eIF2 α sensor kinase, CpcC, to result in increased translation of the CPC transcriptional effector, CpcA (Sasse et al., 2008). CpcA activates signal transduction pathways to promote amino acid biosynthesis, and this process contributes to pathogenicity as deletion of CpcA resulted in attenuated virulence in a murine model of pulmonary aspergillosis (Krappmann et al., 2004). In *C. albicans*, the GAAC response is mediated by the CpcA orthologue Gcn4. Its expression is tightly regulated by transcriptional and translational control mechanisms, including inhibition by TOR, as it regulates critical virulence determinants that are induced by amino acid starvation (Sundaram and Grant, 2014; Bastidas et al., 2009; Tripathi et al., 2002). Ingestion of *C. albicans* by neutrophils results in a Gcn4- dependent induction of arginine biosynthesis, revealing that the fungus experiences amino acid starvation within these immune effector cells (Rubin-Bejerano et al., 2003). As in *A. fumigatus*, the transcriptional activator is necessary for full virulence in a model of candidiasis (Brand et al., 2004). To date an orthologue of CpcA/Gcn4 has not been identified in *C. neoformans* (Garbe and Vylkova, 2019).

C. albicans possesses a sensor system capable of sensing extracellular amino acid availability and subsequently enhancing the breakdown and import of external proteins (Zhang et al., 2020). The so called SPS sensor complex comprises membrane bound Ssy1, which senses extracellular amino acids and relays the signal to the other components, scaffold protein Ptr3, and the signalling endopeptidase Ssy5 (Brega et al., 2004; Martínez and Ljungdahl, 2005). Ssy5 removes cytoplasmic retention domains from the transcription factors Stp1, that stimulates extracellular protein degradation (via enzymes such as the major secreted aspartyl proteinase (SAP) Sap2) and oligopeptide transport (as Opt1), and Stp2, which increases expression of amino acid permeases including transceptors such as Gap1 and Gap2 (Martínez and Ljungdahl, 2005; Silao et al., 2019). The functionality of Ssy1 and amino acid permeases (AAPs) are dependent on a chaperone, Csh3, the deletion of which prevents amino acid uptake and virulence in a murine model (Martínez and Ljungdahl, 2004). Levels of Stp1, but not Stp2, are controlled by Gln3 and Gat1- mediated NCR to allow amino acids to be utilized as a preferred nitrogen source over extracellular proteins when abundant (Dabas and Morschhäuser, 2008; Martínez and Ljungdahl, 2005). In vivo evidence supports the critical role of this pathway in nutrient acquisition within the host as SAPs, including Sap2, contribute to the virulence of *C. albicans* in models of candidiasis (Hube et al., 1997; Sanglard et al., 1997; De Bernardis et al., 1999; Staib et al., 2002). A subset of Stp2- regulated genes, including amino acid biosynthetic pathways and transporters, are controlled independently of Ssy1-mediated activation (Miramón et al., 2020). This might explain Stp2's significant contribution to virulence in models of candidiasis (Miramón et al., 2020; Miramón and Lorenz, 2016; Vylkova and Lorenz, 2014). Deletion of Stp2 results in increased activation of Gcn4 and sensitivity to rapamycin, highlighting the interconnected nature of the TOR, GCN and SPS nutrient response pathways (Böttcher et al., 2020). The SPS system also facilitates the amino acid driven neutralization of the acidic environment encountered upon phagocytosis, and is therefore critical to normal macrophage resistance in *C. albicans* (Miramón and Lorenz, 2016; Vylkova and Lorenz, 2014). The SPS system has not been characterized in *A. fumigatus* or *C. neoformans*, although putative orthologs of a very limited number of the proteins involved have been identified (Garbe and Vylkova, 2019; Fernandes et al., 2015).

The genomes of pathogenic fungi encode numerous enzymes which allow the utilization of external proteins as nutrient sources. *C. albicans* possesses 10 SAPs which produce oligopeptides and individual amino acids from the degradation of extracellular proteins and eight oligopeptide transporters and 22 AAPs that facilitate their uptake (Monod et al., 2002; Naglik et al., 2003; Ramachandra et al., 2014; Reuß and Morschhäuser, 2006; Sychrová and Souciet, 1994; Kraidlova et al., 2011). Proteases are critical to amino acid acquisition and the penetration of the blood brain barrier by *C. neoformans*, and therefore for its pathogenicity (Vu et al., 2014; Xu et al., 2014a; Clarke et al., 2016). One of *C. neoformans*' six predicted oligopeptide transporters (OPTs), Opt1 has also been implicated in the regulation of virulence factors and four of its 10 AAPs play a role in virulence (Homes et al., 2016; Martho et al., 2016). *A. fumigatus* encodes a particularly high number (>100) of putative proteases that, as mentioned before, have redundant functions, making it difficult to establish their importance for virulence but are known to be implicated in allergic responses (Garbe and Vylkova, 2019; Gifford et al., 2002; Druey et al., 2020; Tomee et al., 1997). *A. fumigatus* proteases are differentially expressed on various nutrient sources, with at least two transcription factors identified, PrtT and XprG, that control their expression, indicating that this fungus can distinguish between complex protein sources and regulate secretion of proteases to exploit them (Farnell et al., 2012; Sharon et al., 2009; Bergmann et al., 2009; Shemesh et al., 2017). It has been proposed that during infection *A. fumigatus* exploits amino acids as C-source, as a methylcitrate synthase deletant (which accumulates propionyl-CoA from the catabolism of valine, isoleucine, and methionine) showed a strong decrease in virulence (Ibrahim-Granet et al., 2008). Interestingly, deletion of all eight *A. fumigatus* OPTs did not inhibit in vitro growth or virulence in a murine model of pulmonary aspergillosis, indicating the existence of unidentified methods of oligopeptide uptake or that the fungus effectively degrades extracellular proteins to individual amino acids (Garbe and Vylkova, 2019; Hartmann et al., 2011).

Lipids

Lipids are a functionally and structurally heterogeneous group of macromolecules that are soluble in nonpolar solvents, insoluble in water and have hydrophobic or amphiphilic properties. Common lipid molecules in cells are fatty acids, phospholipids, sphingolipids, glycerolipids, and sterols (Huang and Freter, 2015).

Fatty acids

Fatty acids are building blocks for other lipids and also act as energy reservoirs and signalling molecules. They have a common basic structure of carboxylic acids with hydrocarbon tails that vary in chain length and the degree of unsaturation. De novo synthesis of fatty acids can take place in the cytoplasm and in the mitochondria, followed by elongation and desaturation in the endoplasmic reticulum (ER). It starts with the carboxylation of acetyl-CoA by the action of ACC1 (cytosol) or HFA1 (mitochondria) to form malonyl-CoA, which serves as the two-carbon building block for the subsequent reactions (Hasslacher et al., 1993; Hoja et al., 2004). Synthesis in the cytosol is carried out by the hexameric fatty acid synthase (FAS) complex, which consists of 6 Fas1p and 6 Fas2p subunits, each exhibiting more than one enzymatic activity (Stoops and Wakil, 1978; Leibundgut et al., 2008). The mitochondrial FAS complex consists of six proteins, each producing only one enzymatic activity (Hiltunen et al., 2010). Both complexes add two carbons from malonyl-CoA to a saturated acyl chain, to produce mostly lipoic acid (mitochondrial), or a chain length up to C18 (cytosolic). Further elongations by the addition of two carbons from malonyl-CoA takes place in the ER by different elongases (Toke and Martin, 1996). Desaturation and hydroxylation also occur in the ER, performed by the acyl-CoA Δ^9 -desaturase Ole1p (Stukey et al., 1989).

Fungal cells can also acquire fatty acids from the environment in a process termed vectorial acylation that links transport with metabolic activation and involves fatty acid transport proteins (FATP) and long-chain acyl CoA synthetases (ACSL) (Black and DiRusso, 2007).

Excess of fatty acids are stored in the form of triacylglycerols, which serve as energy reservoirs and are stored in distinct organelles called lipid droplets (Daum et al., 2007). Mobilization of triacylglycerols is based on the action of three lipases Tgl3p, Tgl4p and Tgl5p (Athenstaedt and Daum, 2003, 2005). Fatty acids can then enter β -oxidation, a catabolic process which in fungi exclusively takes place in peroxisomes and that produces a high number of ATP molecules (Hiltunen et al., 2003).

Phospholipids

Phospholipids have an amphipathic character due to their structure. They consist of a diacylglycerol as hydrophobic moiety and different polar head groups at the hydrophilic side. Diacylglycerol is esterified in the positions 1 and 3 with combinations of fatty acids and the head group is linked to the 2 position, which constitutes the diversity of phospholipids. Due to their amphipathic properties, phospholipids form bilayers, which are the basis of biological membranes (Daum et al., 1998). The major phospholipids in *S. cerevisiae* are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylserine (PS) (Klug and Daum, 2014).

In this model fungus, biosynthesis of phospholipids starts with the synthesis of phosphatidic acid (PA). PA is generated by acylation of glycerol 3-phosphate by Sct1p (GAT2) and Gpt2p (GAT1) to form lyso-PA and subsequent acylation by acyltransferases Slc1p, Slc4p (Athenstaedt and Daum, 1997; Jain et al., 2007; Benghezal et al., 2007). Sct1p and Gpt2p can also use dihydroxyacetone phosphate (DHAP) as a substrate to form acyl-DHAP, which is then converted to Lyso-PA by the reductase Ayr1p (Zheng and Zou, 2001; Athenstaedt and Daum, 2000). PA serves as a central metabolite in the de novo synthesis of all phospholipids by a complex metabolic network that has substantial differences with humans (Klug and Daum, 2014; Pan et al., 2018). At least three enzymes of the pathway, PS synthase, PS decarboxylase, and phospholipid methylase, have been described as potential antifungal targets (Cassilly and Reynolds, 2018).

Sphingolipids

Sphingolipids are also important components of cell membranes and act as signalling molecules. In *S. cerevisiae*, de novo sphingolipid synthesis begins with the condensation of a serine and a fatty acyl-CoA, normally palmitoyl-CoA, by the action of the serine palmitoyl-transferase complex, which consists of three enzymes encoded by LCB1, LCB2, and TSC3 (Nagiec et al., 1994; Gable et al., 2000). The product of this reaction, 3-ketodihydrosphingosine, is converted to dihydrosphingosine by the 3-ketosphinganine reductase Tsc10p (Beeler et al., 1998). Dihydrosphingosine can be hydroxylated by Sur2p to form phytosphingosine. Then, the ceramide synthase complex, comprising Lag1p, Lac1p and Lip1p, catalyzes acyl-CoA-dependent acetylation of dihydrosphingosine or phytosphingosine with long fatty acids to yield dihydroceramide and phytoceramide, respectively (Schorling et al., 2001; Vallée and Riezman, 2005). Complex sphingolipids are formed by addition of an inositol phosphate group to ceramide, catalyzed by the inositolphosphoryl ceramide synthase Aur1p (Nagiec et al., 1997). Inositol-P-ceramide can then be mannosylated by Csg1p, Csg2p and Csh1p complex to form mannose-inositolphosphoryl ceramide and then a second inositol phosphate group can be attached by Ipt1p to synthesize mannose-diinositolphosphoryl ceramide (Uemura et al., 2003; Dickson et al., 1997).

Sterols

Sterols are fundamental components of cell membranes, regulating their fluidity and dynamically aggregating in conjunction with sphingolipids to form lipid rafts. The major sterol in fungi is ergosterol, the equivalent of mammalian cholesterol.

Ergosterol is synthesized through a complex pathway that begins with acetyl-CoA and involves more than 20 enzymes (Klug and Daum, 2014). In addition, some species as *A. fumigatus* encode multiple genes for the same key enzymatic activities (Mellado et al., 2001; Alcazar-Fuoli et al., 2006). Balance and regulation of sterol synthesis is important to avoid accumulation of free sterols which may become toxic for the cell. Such regulation of sterol levels is mainly achieved by feedback mechanisms at transcriptional, translational and post-translational levels (Espenshade and Hughes, 2007). For instance, hydroxy-3-methylglutaryl-CoA (HMG-

CoA) is reduced to mevalonate by HMG-CoA reductases and this step is subjected to feedback inhibition by sterol intermediates through enzyme proteasome dependent degradation (Burg and Espenshade, 2011). Interestingly, there seems to be a strong link between sterols and oxygen, where sterols act as oxygen sensors, serve as defense against oxidative damage and their synthesis being an intensive oxygen-consuming process (Galea and Brown, 2009). The Sterol Regulatory Element Binding Protein (SREBP) class of transcription factors maintain cellular sterol levels through transcriptional activation of target genes upon steroid depletion. In addition, SREBP factors monitor oxygen dependent sterol synthesis as an indirect measure of oxygen availability and are required to adapt to low oxygen (Hughes et al., 2005; Todd et al., 2006). These factors are essential for *A. fumigatus* and *C. neoformans* virulence (Willger et al., 2008; Chung et al., 2014; Chang et al., 2007; Chun et al., 2007). Apparently, *C. albicans* does not encode SREBPs orthologs, while its *UPC2* product seems to carry out similar functions (Silver et al., 2004; MacPherson et al., 2005).

Excess sterols are acetylated and stored as sterol-esters in lipid droplets (together with triacylglycerols) (Yu et al., 1996; Kim et al., 2004; Daum et al., 2007). Sterol-esters can be mobilized by various hydrolytic enzymes, which can help to balance shortage of sterols (Daum et al., 2007; Brown et al., 1980).

Polyketides

Polyketides are a rare type of lipids, normally referred as secondary metabolites, that have a biosynthetic chemistry highly similar to fatty acids (Smith and Tsai, 2007; Chiang et al., 2010). This diverse group of compounds has great significance for the virulence of fungal pathogens. Particularly, *Aspergillus* species can produce many polyketides, by action of polyketide synthase enzymes type I, with high relevance to human health (Bhetariya et al., 2011). For example, *A. flavus* and *A. parasiticus* produce aflatoxin, by a polyketide pathway consisting of at least 27 reactions, which is a toxin that contaminates food and causes hepatotoxicity, teratogenicity, and immunotoxicity (Caceres et al., 2020; Kumar et al., 2017). Furthermore, *A. fumigatus* produces (among approximately 8 polyketides) DHN-melanin, which covers spores and that is known to be a very important fungal virulence factor (Bignell et al., 2016; Heinekamp et al., 2013; Akoumianaki et al., 2016).

Sugar metabolism

As detailed in the carbon metabolism section, glucose is the preferred carbon source for fungi. Glucose is catabolized through glycolysis pathway to form precursors of other macromolecules (such as lipids and amino acids) and to obtain energy through fermentation and/or the TCA cycle and respiration. Glucose can also be metabolized to enter the pentose phosphate pathway to create redox equivalents and to form nucleotides.

When glucose is not available, fungi can obtain carbon and energy from a broad range of fermentable and non-fermentable sources (Ene et al., 2014). These alternative carbon sources can fuel anabolism by generating glucose and its derivatives through gluconeogenesis. In order to assimilate non-fermentable two-carbon sources (such as ethanol and acetate), fungi use the glyoxylate cycle. This is basically a shunt in the TCA cycle in which two enzymes (isocitrate dehydrogenase and α -ketoglutarate dehydrogenase) are excluded and the alternative glyoxylate cycle comprises two key enzymes: isocitrate lyase and malate synthase. In essence, isocitrate lyase breaks down isocitrate (C6) to glyoxylate (C2) and succinate (C4), and malate synthase condensates the released glyoxylate with acetyl-CoA (C2) to generate malate (C4). In this way, malate produced from C2 compounds can replenish the TCA cycle or serve as the precursor of oxaloacetate, an essential substrate for gluconeogenesis (Dunn et al., 2009).

In fungi, two glucoses can join via a α,α -1,1-glycosidic linkage to form the disaccharide trehalose. Human-pathogenic fungi use one or two biosynthetic pathways. The canonical pathway involves two enzymes: trehalose-6-phosphate synthase (Tps1p) and trehalose-6-phosphate phosphatase (Tps2p). Tps1p transforms UDP-glucose and glucose-6-phosphate into UDP and trehalose-6-phosphate, which is then converted by Tps2p into trehalose and free inorganic phosphate (Pi). The non-canonical pathway, present in some filamentous fungi, consists in one enzyme, trehalose phosphorylase (TreP) that converts glucose-1-phosphate (G1P) and glucose into trehalose (Shinohara et al., 2002; Thammahong et al., 2017b). Trehalose is an important molecule in fungal biology and required for virulence of *C. albicans*, *C. neoformans*, *C. gattii* and *A. fumigatus* (Zaragoza et al., 1998; Petzold et al., 2006; Ngamskulrungron et al., 2009; Al-Bader et al., 2010; Puttikamonkul et al., 2010). It is proposed to serve as energy reserve, although there is still some controversy on this topic (Wiemken, 1990; Thammahong et al., 2017b). Trehalose seems to play an important role as a general stress protectant in fungi, providing protection against dehydration, thermal stress and free radicals (Thammahong et al., 2017b).

The requirement of specific pathways for infection depends on the nutritional niche that the fungal pathogens encounter during infection (Barelle et al., 2006; Price et al., 2011). For instance, glycolysis is important for the virulence of most fungal pathogens, but not for the intracellular pathogen *Histoplasma capsulatum* (Shen et al., 2020). The glyoxylate cycle is required for *C. albicans* and *C. glabrata* virulence, but not in *C. neoformans* or *A. fumigatus* (Lorenz and Fink, 2001; Barelle et al., 2006; Chew et al., 2019; Rude et al., 2002; Idnurm et al., 2007; Schöbel et al., 2007; Olivas et al., 2008). In addition, metabolic flexibility and temporal adaptation are essential traits for pathogenesis. For instance, *C. albicans* adapts its metabolism to different host niches and can assimilate glucose and alternative carbon sources simultaneously, which provides an advantage in the interaction with the host (Brown et al., 2014a; Sandai et al., 2012; Tucey et al., 2018). *A. fumigatus* seems to perform both fermentation and respiration during infection, and a temporal metabolic plasticity of the assimilation and metabolization of carbon sources is fundamental for its virulence (Grahl et al., 2011, 2012; Beattie et al., 2017). Such an adaptation to different carbon sources is also important for *C. neoformans* virulence (Hu et al., 2008a).

Cell wall

The metabolism of sugars is particularly relevant in fungi as polysaccharides are core components of their cell wall. These are dynamic structures, pivotal for cell viability, morphogenesis, and pathogenesis. Indeed, the structure of cell wall adapts to the environment, which is crucial for fungal survival under conditions of infection (Shepardson and Cramer, 2013). In particular, there is a directly link of the carbon source with the cell wall architecture, which modulates fungal virulence (Ene et al., 2012; Ballou et al., 2016). Major cell wall polysaccharides include glucans, chitin and mannans. Glucans are polysaccharides of D-glucose linked by glycosidic bonds. Common glucans in cell walls are β -1,3-glucan, α -1,3-glucan, β -1,6-glucan and mixed β -1,3-/ β -1,4-glucans. Chitin is a long-chain polymer of N-acetylglucosamine, Mannans are linear polymers of mannose, usually with α (1,6)-mannoside linear links and α (1,2) or α (1,3) linked branches (Gow et al., 2017). Being in contact with the exterior, these molecules are important pathogen associated molecular patterns (PAMPs) that are recognized by host pathogen recognition receptors (PRRs) to induce and orchestrate innate and adaptive immune responses. For instance, the C-type lectin receptor Dectin-1 recognizes β -glucans, a variety of receptors can recognize different mannans and mannosylated moieties (C-type receptors as Dectin-2, Dectin-3, Mincle, Mannose receptor (MR) or DC-SIGN and Toll-like receptors as TLR-2 or TLR-4), and chitin has been suggested to be a ligand for NOD2 and TLR-9 (Brown and Gordon, 2001; Lionakis et al., 2017; Wagener et al., 2014).

Nucleotides

Nucleotides are critical players in a myriad of cellular processes. Purine and pyrimidine nucleotides are basic components of nucleic acids, major energy carriers, signalling molecules (as cyclic AMP) and precursors for the synthesis of cofactors such as Nicotinamide adenine dinucleotide (NAD) and SAM. Purine and pyrimidine biosynthesis pathways are highly conserved in prokaryotes and eukaryotes.

Pyrimidine de novo biosynthesis requires 6 enzymatic activities and consumes 2 ATPs (Garrett and Grisham, 2010). In *S. cerevisiae*, the pathway is regulated at the enzymatic level through feedback inhibition of the first committed enzyme of the route (Ura2) by the final product UTP and at the transcriptional level by the zinc-finger transcription factor Ppr1, which can sense levels of intermediates of the pathway (Jones and Fink, 1982; Kammerer et al., 1984; Flynn and Reece, 1999). Transcription of URA2 seems to be Ppr1-independent and be instead controlled by alternative transcription start-sites that lead to production of unstable mRNAs ("cryptic unstable transcripts") when there is sufficient uracil (Thiebaut et al., 2008). Interestingly, Ppr1 has a different function in *C. albicans* and *A. nidulans* (UaY), where it controls purine catabolism (Suárez et al., 1995; Tebung et al., 2016). Therefore, even if transcription of the genes responds to the concentration of pyrimidines, the exact mechanism has not described (Aleksenko et al., 2002). The pyrimidine biosynthetic pathway has been shown to be important for *C. neoformans*, *A. fumigatus*, *H. capsulatum*, and *C. albicans* virulence (de Gontijo et al., 2014; D'Enfert et al., 1996; Retallack et al., 1999; Cole et al., 1995; Brand et al., 2004).

Purine de novo biosynthesis requires 11 enzymatic activities and consumes 6 ATPs (Garrett and Grisham, 2010). The pathway is regulated at the transcriptional level by the regulators Bas1 and Bas2/Pho2 (Daigan-Fornier and Fink, 1992). These two factors need to interact to activate transcription, which is promoted in the presence of the metabolite intermediate SAICAR. In low adenine concentrations, levels of ADP and ATP decrease, liberating feedback inhibition of the first enzyme of the pathway (Ade4), which in turn increases the levels of SAICAR (Rébora et al., 2001). Transcription of genes for GTP synthesis is independently regulated by guanine (Escobar-Henriques and Daignan-Fornier, 2001). In addition, the gene encoding the first enzyme of the branch (IMD2) is regulated by cryptic unstable transcripts, via GTP-dependent start site selection (Davis and Ares, 2006; Steinmetz et al., 2006; Kuehner and Brow, 2008). Integrity of the biosynthetic pathway has been shown to be important for *C. albicans*, *C. neoformans* and *A. fumigatus* virulence (Donovan et al., 2001; Jiang et al., 2010; Rodriguez-Suarez et al., 2007; Morrow et al., 2012; Blundell et al., 2016; Chitty et al., 2017).

As building blocks of DNA, nucleotide biosynthesis is regulated by the growth phase. When cells enter stationary phase, several genes of the pathway are downregulated and some enzymes become inactivated (Escobar-Henriques et al., 2003; Escusa et al., 2006; Narayanaswamy et al., 2009). In contrast, nucleotide biosynthetic genes are upregulated under growth proliferation conditions (Walvekar et al., 2018).

Most fungi can use purines and some can use pyrimidines as nitrogen source (Rasmussen et al., 2014). The purine catabolic pathway is present in most filamentous fungi, while it is degenerated in most yeasts (Pantazopoulou and Diallinas, 2007). The pathway, which consists in 6 enzymatic reactions that sequentially degrade xanthine to ammonia, is present in all human fungal pathogens except *Pneumocystis jirovecii*, but its relevance for virulence has only been tested in *C. neoformans* (Chitty and Fraser, 2017; Cissé et al., 2014; Cox et al., 2000). Purines and pyrimidines are taken up by transporters belonging to three different protein families: the nucleobase cation symporter family 1 (NCS1 or PRT), the nucleobase-ascorbate transporter family (NAT or NCS2) and the AzgA-like family (Pantazopoulou and Diallinas, 2007). Transcription of most genes encoding the enzymes involved in purine catabolism and uptake are regulated by nitrogen catabolite repression and the positive-acting transcription factor UaY (Scazzocchio et al., 1982; Scazzocchio, 1994).

Prospectives for new antifungal treatments

As highlighted in this chapter, many points within primary metabolism have been described to be crucial for fungal growth and/or virulence. In this section, we provide an overview of some of the most promising targets identified from primary metabolism and the existing novel agents developed so far against them.

Targeting the central routes of carbon, nitrogen and sulfur metabolism have been repeatedly suggested as a promising strategy to fight fungal infections (Bachhawat and Yadav, 2010; Traynor et al., 2019). For example, sulfite reductase, cystathionine γ -synthase and methionine synthase, in the sulfur assimilation and trans-sulfuration pathway, are considered good targets for the development of novel antifungals (Scott et al., 2020; Jastrzębowska and Gabriel, 2015); active agents have already been described, as azoxybacilin to inhibit gene expression of sulfite reductase (Aoki et al., 1996), or anilino-pyrimidines, which apparently inhibit cystathionine- γ -synthase and/or cystathionine- β -synthase (Jastrzębowska and Gabriel, 2015).

Targeting acquisition of microelements is also considered a promising strategy to fight fungal infections. Blockage of iron acquisition, either by direct inhibition of uptake systems/biosynthetic enzymes or by iron chelation appears to be a good strategy to treat fungal infections and augment antifungal therapy (Bairwa et al., 2017). In addition, siderophores have the potential to be exploited for diagnosis, both by its direct detection as a biomarker in urine or by the use of radiolabelled siderophores as trojan horse for the targeted imaging of infection by positron emission tomography (Skriba et al., 2018; Hoenigl et al., 2019; Petrik et al., 2012, 2014). Actually, specific internalization of antifungal drugs by siderophore transporters opens new possibilities for specific delivery, as described for the novel drug in development VL-2397 (formerly ASP2397) (Dietl et al., 2019). Additionally, compounds with zinc-chelation activity have been found to have potent antifungal activity in murine models of infection (Clark et al., 2018; Cohrt et al., 2018; Laskaris et al., 2016; Li et al., 2018; Vicentefranqueira et al., 2015; Simm and May, 2019).

Interference with calcium homeostasis is one of the best studied new strategies to fight fungal infections. In particular, inhibiting calcineurin with compounds such as cyclosporine-A or tacrolimus (FK506) has been demonstrated to be an effective antifungal therapy (Juvvadi et al., 2017, 2019) and to synergize with azoles (Uppuluri et al., 2008; Li et al., 2019b). The main holdback is that calcineurin is not a fungal specific target and consequently these compounds are immunosuppressive. Encouraging, a novel promising compound, APX879, with higher specificity and lower toxicity was recently developed (Juvvadi et al., 2019). Other approaches to interfere with calcium homeostasis have also shown value as antifungal therapies, as the use of the calcium-channel blockers verapamil or disruption of activity of the Golgi transporter Pmr1 (Yu et al., 2013; Gupta et al., 2003).

Amino acid metabolism is directly and indirectly crucial for fungal virulence. Many of its biosynthetic pathways have been shown to be required for pathogenicity and thus blocking them is proposed as a promising antifungal strategy, with many inhibitors already described (Jastrzębowska and Gabriel, 2015; Amich and Bignell, 2016). Proline catabolism has been implicated in *C. neoformans* ROS homeostasis and production of virulence factors and in *C. albicans* filamentation (Lee et al., 2013a; Silao et al., 2019). Disruption of the tryptophan, threonine, isoleucine/valine and leucine biosynthetic pathways impacts *C. neoformans* viability and/or virulence (Do et al., 2015; Kingsbury and McCusker, 2008; Fernandes et al., 2015; Kingsbury et al., 2004). In *C. albicans*, disturbance of the threonine and branched-chain amino acid biosynthetic pathways reduces virulence in mice (Kingsbury and McCusker, 2010b, a) and methionine biosynthesis intertwines metabolism, signalling and virulence (Maidan et al., 2005; Schrevens et al., 2018) hyphal morphogenesis (Vylkova et al., 2011; Schrevens et al., 2018; Silao et al., 2019) and biofilm formation (Rajendran et al., 2016). In *A. fumigatus*, interference with methionine synthase triggers a complex metabolic imbalance that causes growth halt and decreased virulence (Scott et al., 2020), the biosynthesis of aromatic amino acids and histidine are crucial for pathogenicity, and arginine biosynthesis impacts on siderophore biosynthesis (Dietl et al., 2020, 2016; Sasse et al., 2016). This all supports the premise that amino acid metabolism presents a promising target for antifungal drug discovery (Amich and Bignell, 2016; Kaldorf et al., 2016). In addition, amino acid transport mechanisms have been recently been proposed as potential antifungal targets (McCarthy and Walsh, 2018).

Lipid metabolism is arguably the major source of antifungal targets. Indeed, several existing antifungals target ergosterol, including the three major classes: azoles, polyenes and allylamines. Azoles, the first line of treatment of *Aspergillus*-related infections, inhibit 14- α sterol demethylase (Cyp51/Erg11), blocking the biosynthesis pathway and causing accumulation of precursor sterols, accumulation of reactive oxygen and nitrosative stress as well as cell wall stress (Ullmann et al., 2018; Patterson et al., 2016; Ghannoum and Rice, 1999; Vandenbosch et al., 2010; Ferreira et al., 2013; Geißel et al., 2018). The polyene Amphotericin-B, which continues to be an important antifungal for the treatment of invasive infections, directly binds ergosterol in the membrane (Gray et al., 2012). The allylamine group of antimycotics inhibit the enzyme squalene epoxidase (Erg1) causing high intracellular squalene concentrations, which seemingly interfere with membrane function and cell wall synthesis (Geißel et al., 2018). Fatty acid synthesis has been proposed as an antifungal target in *C. neoformans* and *C. parapsilosis* (Chayakulkeeree et al., 2007; Nguyen et al., 2009). Fatty acids seem to serve as carbon source for *C. albicans* during infection but not to *A. fumigatus* (Lorenz and Fink, 2001; Ramírez and Lorenz, 2007, 2009; Schöbel et al., 2007). In addition, *C. albicans* morphogenesis (an important virulence factor) is influenced by extracellular fatty acids (Noverr and Huffnagle, 2004). Hydrolysis of phospholipids by phospholipases releases various types of molecules that are involved in signalling and that are important for fungal virulence (Köhler et al., 2006; Barman et al., 2018; Ghannoum, 2000; Park et al., 2013). A few compounds to target fungal phospholipase B have been described in vitro (Ng et al., 2006; Ganendren et al., 2004). Sphingolipids play essential roles in fungal virulence (Rittershaus et al., 2006; Bertini et al., 2007; Oura and Kajiwar, 2008); however, targeting sphingolipids is not easy as many biosynthetic steps between mammals and fungi are conserved (Rollin-Pinheiro et al., 2016). One of the most promising drug target candidates is inositolphosphoryl ceramide synthase, a fungal specific enzyme against which various inhibitors with strong antifungal effect have already been described (Sugimoto et al., 2004; Mandala et al., 1998, 1997; Aeed et al., 2009; Wuts et al., 2015; Harris et al., 1998). In addition, a novel family of drugs that inhibit glucosylceramide synthesis has been found to have broad antifungal activities (Mor et al., 2015).

Targeting sugar metabolism, including energy producing routes is also a promising antifungal strategy. As a prominent example, the novel antifungal drug Arylamidine T-2307, which has broad spectrum antifungal activity in vitro and in vivo, acts by selective disruption of yeast mitochondrial function (Mitsuyama et al., 2008; Yamashita et al., 2019). Several other enzymes of glucose

metabolism have been proposed as antifungal targets, with various specific inhibitory compounds shown to exert antifungal activity (Chen et al., 2020). Moreover, the cell wall is an attractive target for antifungal therapeutics, as it is fungal specific and thus treatment might be associated with low host toxicity. Echinocandins, which are still the newest class of antifungal agents approved for clinical treatment, act through inhibition of the catalytic subunit of the β -(1,3)-D-glucan synthase, leading to osmotic instability and cell death (Denning, 2003; Odds et al., 2003). The novel drug Fosmanogepix (APX001) targets Gwt1p, which catalyzes an early step in glycosylphosphatidylinositol (GPI)-anchor biosynthesis, resulting in a defect in cell wall assembly (Hata et al., 2011; Umemura et al., 2003). Targeting chitin synthesis is considered a promising strategy for the development of novel drugs (Li et al., 2019a, b; Nix et al., 2009; Kovács et al., 2019). Enzymes related to trehalose biosynthesis have been shown to modulate chitin biosynthesis, and targeting them has also been proposed as an attractive strategy to develop novel antifungals (Thammahong et al., 2017a, b, 2019; Vahedi-Shahandashti and Lass-Flörl, 2020). Galactosaminogalactan, an *A. fumigatus* and *A. flavus* specific heteropolysaccharide with multiple immunomodulatory activities, has been proposed as a good target for novel therapeutics (Speth et al., 2019).

Finally, targeting nucleotide metabolism is as well a promising strategy to fight fungal infections. Indeed, the novel drug Olorofim (formerly F901318) targets dihydroorotate dehydrogenase, the enzyme catalyzing the fourth step of the pyrimidine biosynthesis pathway, and is currently undergoing clinical trials (Oliver et al., 2016). Furthermore, this pathway connects with cell integrity and potentiates action of the antifungal amphotericin-B (Banerjee et al., 2014, 2016). Besides, fungal purine biosynthesis can be targeted by anticancer and immunosuppressive agents such as mycophenolic acid (which inhibits Inosine 5'-monophosphate dehydrogenase, IMPDH, in the de novo synthesis of guanosine) (Rodriguez-Suarez et al., 2007; Köhler et al., 2005; Morrow et al., 2012).

Conclusions

In this chapter we have provided an in-depth overview of fungal primary metabolism, focusing on human pathogens (Fig. 1). We have highlighted the many processes that are known to be relevant for virulence and specified those that are considered promising for the development of novel therapies. The high number of possible metabolic targets supports the idea that primary metabolism is a paramount virulence trait in pathogenic fungi. Many of these targetable metabolic processes are fungal specific, suggesting the possibility to develop new drugs with low host toxicity. Interestingly, the multitude of points in the metabolism that can be attacked, even in the same pathway or convergent pathways, multiplies the possibilities to develop combinatorial strategies to maximize efficacy of treatment and to reduce the emergence of resistance. In addition, as many of the processes are conserved among the fungal kingdom, pan-fungal approaches can likely be developed, including therapies for opportunistic fungal species without obvious virulence factors to target. Nevertheless, it is evident that there are many gaps in our understanding of fungal metabolism that need to be filled to fully exploit the potential of metabolism to fight fungal infections. Particularly, it is clear that there are significant differences among the various pathogenic species, and we have very little knowledge about the specifics in fungal pathogens other than “the big four”. Hence, fungal primary metabolism remains an active and vibrant research field that holds the promise to provide novel options for the development of antifungal therapies.

Fig. 1 Primary metabolism of human fungal pathogens directly links with virulence. The specific host niche in which the pathogen locates determines the nutritional milieu and the environmental conditions to which the fungus is exposed. Both directly impact primary metabolism, the regulation of the acquisition of macro- and micronutrients and thus the metabolism of the molecules of life. A balanced primary metabolism supports the biosynthesis and metabolism of macromolecules, underlie viability and confers the capacity to thrive and grow in the host tissues, therefore sustaining virulence of fungal pathogens. Primary metabolisms of fungi and mammals have significant differences, which highlights the opportunities to develop specific (non-toxic) drugs. Within the primary metabolism of fungal pathogens, there are many commonalities, which suggests that pan-fungal drugs can be developed. Nevertheless, there are as well species specific differences, which in fact are not well understood yet. Finally, the multitude of potential targets in primary metabolism multiplies the possibilities to develop combinatorial strategies to maximize efficacy of treatment and to reduce the emergence of resistance.

Acknowledgment

We would like to thank Prof Sven Krappmann for critical review of this book chapter and express our deep gratitude for his constant help, support and encouragement.

Introduction

The continuous exposure of the human body to bacteria requires constant monitoring. The most obvious reason for this is to prevent infection, but the most relevant reason is to provide up to the minute environmental samples to educate the immune system on “dangerous” or threatening materials and to differentiate those from innocuous substances or microorganisms that actually provide an advantage to the host. Nowhere is this more obvious than in the gut where current estimates suggest there are at least an equal number of bacteria as human cells (Sender et al., 2016). In comparison, certain bacteria such as *Salmonella enteritidis*, cause disease following a dose as small as 100 cfu. Understanding the differences in this dramatic contrast in immune responses is important for host development and survival and is the subject of this review.

It is also clear that a number of variables exist that affect the immune response that will be impossible to cover in detail, but we have drawn attention to many (Table 1). Therefore, we will not go through immunity to every bacteria, rather we will give a temporal view of the immune response describing each mechanisms within a generalized immune response to bacteria and provide examples of organisms that are targeted by that mechanism. In this case, immune responses against bacteria, will follow three lines including (i) Barriers-physical, chemical and microbiological mediators and cells that block bacterial colonization (ii) innate immunity- receptors and cells that respond immediately over a broad range of specificities and (iii) adaptive immunity-mediators and cells that have a delayed response but have a very narrow range of specificity tailored to the infectious bacteria. These lines of defence work in sequence against each individual organisms, but may overlap depending on the number of infecting organisms.

Table 1 Summary of factors affecting protective immunity to bacteria.

Host	Bacteria
• Body site/route of inoculation/infection • Systemic or local infection • First or subsequent infection • Vaccination • Age • Immunocompromise or immunosuppression • Mucosal immunity	• Dose/number inoculated • Commensal or pathogen • Extracellular or intracellular phase • Virulence factors • Evasion mechanisms • Biofilm production • Antimicrobial resistance • Growth/nutrient requirements

Each bacteria will produce an individualized response, but generalizations can be made due to the property of the immune system in recognizing conserved structures.

Barriers: Repelling and restriction of bacterial infections

The important sites forming the first line of defence as barriers to bacterial infection include the skin, respiratory tract and gastrointestinal tract. Here barriers may be defined as chemical “physical or anatomical,” and microbiological. Nowhere is chemical anti-bacterial immunity more easily demonstrated, than in the secretions from the fluids bathing these sites (Fig. 1). One hundred years ago, Alexander Fleming made the observation that agar plates supplemented with “imbedded tears” had antibacterial activity, identifying “lysozyme” in the process (Fleming, 1922). More recently, Glaser and colleagues identified that the skin protein “psoriacin” has anti-bacterial activity against *E. coli* (Glaser et al., 2005). These visual observations summarize a collection of large and small antimicrobial proteins and peptides present in bodily secretions that lyse and kill bacterial cells. These agents may be present in many areas or anatomically restricted to a few. Thus, lysozyme, lactoferrin, and the cathelicidin, LL-37 are found in the mucosal epithelium like the mouth, intestine, respiratory and urogenital tract. In addition, to these sites, secretory leukocyte protease inhibitor (SLPI), Trappin-2, S100 proteins (such as psoriacin and calprotectin), the α and β defensins can be found in the skin. The surfactant molecules SP-A and SP-D are largely confined to the respiratory tract and the regenerating-islet derived (Reg)-3 β / γ proteins are predominantly found in the intestinal tract. Similarly, histatins and dermcidin are largely confined to the saliva and skin respectively. Many of these proteins are produced constitutively, but can also be induced in response to bacterial stimulation.

Despite being overlooked when discussing immunity to bacterial infection, anatomical factors provide some of the most efficient non-specific host mechanisms to remove pathogenic bacteria. Throughout the respiratory tract, physical defences at the barrier interface include cough and sneeze reflexes which have dramatic power in expelling foreign respiratory pathogens (Bonvini and Belvisi, 2017; Bourouiba et al., 2014; Bourouiba, 2020; Duguid, 1945).

Please see video link in Relevant Websites section.

These reflexes are induced by direct (irritants/bacteria) or indirect (by host derived products) stimulation of sensory vagal and trigeminal nerves respectively. Studies to date have implicated the transient receptor potential (TRP) family of ion channels in this process (Bonvini and Belvisi, 2017) which has recently been shown to be activated by bacterial products (Meseguer et al., 2014).

Fig. 1 Barrier secretions protect against bacterial infection. Panel 1: Agar embedded “tears” in the central circle clearing a lawn of *M. lysodeikticus* (*Micrococcus luteus*) in Fleming’s seminal studies. Panel 2: Psoriacin protects the skin against pathogens. Washed (left) and gloved (right) fingertips were inoculated with 10^4 cfu/mL *E. coli* and incubated for 30 min. Then fingertips were pressed into agar and the plate incubated for 24 h. Note the growth inhibition in the washed hands and the uninterrupted growth in the gloved hand. Antibacterial activity of barrier fluids: Fleming A (1922) On a remarkable bacteriolytic element found in tissues and secretions. *Proceedings of the Royal Society B (Biological Sciences)* 93: 306–317; Glaser R, Harder J, Lange H, Bartels J, Christophers E, and Schroder JM (2005) Antimicrobial psoriacin (S100A7) protects human skin from *Escherichia coli* infection. *Nature Immunology* 6: 57–64.

In contrast, a more subtle but equally effective mechanisms are employed by the mucociliary apparatus to defend the lung against bacterial pathogens. Composed of tiny hair-like projections called cilia, bathed in low viscosity periciliary fluid and an upper mucus layer, the mucociliary system is synchronized to direct mucus associated bacteria and particles to the oro-pharynx for swallowing. The system is present in both the nasal and bronchial tracts, moving in opposite directions, and toward the oro-pharynx. The physiological importance of the mucociliary escalator is highlighted in the rare autosomal recessive disorder primary ciliary dyskinesia (PCD) where cilia are immotile or unable to synchronize resulting in recurrent chronic infections and inflammation of the respiratory tract (Lucas et al., 2020). In the gastrointestinal tract, the emphasis on continued movement remains important. Smooth muscle peristalsis not only pushes food along the gut but discourages bacterial adhesion to the digestive tract wall and encourages the appropriate growth of microbiota (Cremer et al., 2016). Mechanisms of emesis (vomiting) allow the rapid expulsion of stomach contents through the oral cavity to protect the host against food poisoning organisms and their toxins (Horn, 2014; Popa et al., 2019; Hu and Nakane, 2014). Likewise, very recent work on the expulsion from the rectum at the other end of the gastrointestinal tract suggest that mechanisms of diarrhea and defecation are essential for successful clearance during the early phase of bacterial infections (Tsai et al., 2017). Changes in the pH and concentrations of digestive enzymes also contribute to restricting bacterial invasion across the gut wall.

Barriers cannot be discussed without reference to the mucus that they secrete, which is largely composed of mucin molecules. These form a heterogeneous group of high molecular weight, polydisperse, richly glycosylated proteins, transcribed from the MUC genes. There are at least 21 genes for mucin proteins in human and mouse and they are either secreted or membrane bound and show anatomical site specificity (Dharmani et al., 2009; Ridley and Thornton, 2018). For instance, the mucociliary escalator of the lung has been shown to express five main mucins including the membrane associated MUC-1, 4, and 16 and the secreted mucins MUC-5B and MUC-5AC. In contrast the major mucin of the gastrointestinal tract is MUC2. The main functions of mucins are in hydration, lubrication and protection (from host proteases) and in host defence. Here they act to restrict bacterial commensals and pathogens from invading the underlying epithelium. These protective functions are observed in MUC2 deficient mice, that have spontaneous colitis (Van der Sluis et al., 2006), dramatic changes in microbiota (Wu et al., 2018) and have a markedly decreased immunity to *Listeria monocytogenes* (Zhang et al., 2021). Consistent with this, MUC5b deficient mice show abnormal lung architecture (Valque et al., 2019) and confirm its requirement for lung defence against multiple bacterial types, including *S. aureus* (Roy et al., 2014).

Microbiological barriers, in the form of commensal flora, often termed “good bacteria” have been known and studied for many decades. However, it is only in the last 10 years that tools to determine the true diversity have been available. While “microbiota” has accepted effects on innate and adaptive immunity, its major activity contributing to the microbiological barrier is colonization resistance (McKenney and Kendall, 2016; van der Waaij et al., 1971). This parameter measures how long an inoculated bacterial pathogen can be detected in the feces of a host for a given dose giving a proxy measure of colonizing ability (van der Waaij et al., 1971). It is also clear that obligate anaerobic bacteria remain vitally important for health, including species such as *Bifidobacterium*, *Akkermansia*, *Bacteroides*, or *Faecalibacterium* (Andrade et al., 2020). However, colonization resistance is ‘expressed in a variety of ways’ (Sorbara and Pamer, 2019; Fehervari, 2019). These may be summarized as (i) passive-through, out-competing other bacteria for space and nutrients; (ii) active-through the production of anti-bacterial factors or processes. At least 6 mechanisms exist for direct colonization resistance (Fig. 2; Sassone-Corsi and Raffatellu, 2015). While the detailed mechanisms remain unknown, recent work suggests that the microbiome can prime two different host response pathways in the intestine and lungs that protect against bacterial pathogens (Solis and Levy, 2020).

Targeting and responding to bacteria

Immune responses to bacteria (and other organisms) can be organized into those that protect and sample the “extracellular” space and those that target and sample the “intracellular” space (Table 2). Coincidentally, bacteria have also been categorized as “extracellular pathogens,” obligate intracellular pathogens and facultative intracellular pathogens. It is now becoming clear over the last 10 years that strict definitions such as this do not fit the bacterial life cycle and survival within the host (Silva, 2012). Thus, it is perfectly reasonable to find traditionally defined extracellular bacteria, such as *S. aureus* and *E. coli* inside the cell. Likewise, studies have also reported on the presence of intracellular bacteria such as *Chlamydia* and *Campylobacter* outside the cell. Indeed, for successful survival the ability to survive and multiply in different cellular niches is vital for a successful organism. It is clear that “the facultative intracellular bacteria” may well account for a great proportion of organisms that interact with a human host (Silva, 2012). Therefore, while immune mechanisms may be characterized in terms of targeting extracellular and intracellular bacteria, the total immune response should be viewed as that targeting different parts of its life cycle in the host. Thus, every bacteria, will spend a different proportion of time inside or outside the cell and will therefore stimulate specific parts of immunity to different extents.

Sensing bacteria inside and outside the cell

The ability to detect bacteria, quickly and reproducibly, is done through host expressed pattern recognition receptors (PRR) (Paul-Clark et al., 2012). There are germ-line encoded receptors that recognize conserved molecular structures, termed pathogen

Fig. 2 Direct mechanisms of colonization resistance against enteropathogens. The microbiota provide a barrier against incoming enteric pathogens via multiple mechanisms. (1) Adhesion exclusion: certain commensals reduce pathogen adherence to the intestinal mucosa. (2) Carbon source limitation: human commensal *E. coli* strain HS and probiotic strain *E. coli* Nissle both metabolize multiple sugar molecules, which limits the availability of nutrients in the gut to certain pathogens. (3) Micronutrient limitation: the probiotic strain *E. coli* Nissle can uptake iron via several mechanisms, limiting its availability to pathogens, such as *Salmonella typhimurium*. (4) Secretion of antimicrobials: commensals act against pathogens by limiting nutrients, as well as by the production of antimicrobial compounds, such as bacteriocins and microcins. (5) Direct delivery of toxins: although not yet demonstrated *in vivo*, commensals can express T6SSs and contact-dependent inhibition systems, means by which to deliver growth-inhibiting toxins to close competitors. (6) Circumventing colonization resistance: pathogens use a variety of virulence factors to colonize the host and cause disease. Direct colonisation resistance. Sassone-Corsi M and Raffatellu M (2015) No vacancy: How beneficial microbes cooperate with immunity to provide colonization resistance to pathogens. *Journal of Immunology* 194: 4081–4087.

Table 2 Summary of major immune mechanisms against extracellular and intracellular bacteria.

Intracellular immunity	Extracellular immunity
• Barriers • ILC/NK cells • CD8, cytotoxic T cells • Th1 immunity • TLRs and NLRs • AMP • Cytokines IFN	• Barriers • Complement • Soluble PRR • IgG, IgM and IgA • Phagocytes/phagocytosis • CD4 T helper lymphocytes • Th17 immunity • TLRs • AMP • Cytokines IL-1, CXCL8, CCL2

Bacteria will be present in both the intracellular and extracellular space. The table lists the important immune components that will target intracellular and extracellular spaces.

Table 3 Toll like receptors and their agonists.

TLR	PAMP	Pathogen	Species
2/1 (heterodimer)	Pam3/Csk4	Synthetic diacylated lipoprotein	Mouse
2/6	FSL-1	Synthetic diacylated lipoprotein	Guinea pig
		Synthetic triacylated lipoprotein	
2	Pam3/Csk4	Gram Pos bacterial cell wall	Mouse
2	LTA, MDP	Mycobacterial	Human/mouse
2	PGN	Extra cellular matrix protein	Human/mouse
2	BCG	Fungal	Human/mouse
2/6	Hyaluronan, biglycan	Bacterial	Human/mouse
2/6	Zymosan		
	MALP-2		
3	Poly I:C	dsRNA viruses	Human
4	LPS	Gram negative bacteria	Human
	Lipid A moiety	LPS moiety	Human
	Ozone	Oxidant	Mouse and human
	BCG	Mycobacterial	Mouse
	Hyaluronan	Extra cellular matrix protein	Human
5	Flagellin	Bacterial flagella	Human
2/6	Zymosan	Fungal	Human/mouse
2/6 (heterodimer)	MALP-2	Bacterial	
7	Imidazoquinolines [imiquimod, resiquimod (R-848) and gardiquimod] isatoribine, loxoribine	ssRNA viruses and nonviral	Human
		Origin (poly dT; thymidine homopolymer phosphorothioate)	Human
			Human
7/8	Resiquimoid (R848), CL097		Human
7/8			Human
8	3M-002/CL-075	ssRNA viruses	Human
		Pure thiazoloquinolone TLR8 agonist	
9	CpG DNA	TLR9 recognizes unmethylated CpG motifs of bacterial and viral DNA	Human
	Imidazoquinoline (852 A), ODN2006		
		Agonists of the TLR9 are major activators of type 1 IFNs (IFN α /b). They can produce other cytokines, for example, IFN-g, IL-6, IL-10 and IL-1ra.	
10/1	Pam3CSK4	Synthetic triacylated lipoprotein	Human
10/2	Zymosan		
11	Profilin	Uropathogenic bacteria	Mouse

Known PRR, organised as a table on TLR and a table on NLR. Paul-Clark MJ, George PM, Gatheral T, Parzych K, Wright WR, Crawford D, Bailey LK, Reed DM, and Mitchell JA (2012) Pharmacology and therapeutic potential of pattern recognition receptors. *Pharmacology & Therapeutics* 135: 200–215.

associated molecular patterns (PAMPs). Therefore, these initial sensing molecules scan for “similarities” between all bacteria. The major PRR for bacteria include the toll like receptors (TLR, [Table 3](#)) and the nucleotide binding and oligomerization (NOD)-like receptors (NLR) ([Table 4](#)).

These two families of PRRs recognize their conserved targets in different parts of the host cell, including the surface, the cytoplasm and within endocytic vesicles and therefore allow detection of bacteria in the extracellular environment and interstitial space together with the intracellular environment and cytoplasmic organelles. Important conserved structures include peptidoglycan (PGN), lipoteichoic acid (LTA), lipopolysaccharide (LPS) and flagellin that bind to TLR-2, TLR-4 and -5 respectively. Numerous cells constitutively express or can upregulate PRR and this together with their anatomical locations provide opportunity for bacterial sensing.

Macrophages

Originating from blood derived monocytes and recruited to reside in tissue spaces, macrophages are regarded as local sentinels and scavengers of the local tissue spaces ([Orecchioni et al., 2019](#); [Mills et al., 2000](#); [Martinez and Gordon, 2014](#); [Murray et al., 2014](#); [Shapouri-Moghaddam et al., 2018](#)). They are the resident “phagocyte” (eating cell) responsible for removing bacteria and dead cells.

Table 4 NOD like receptors and their agonists.

Family	Members		Location	Agonists
	Human	Mouse		
NLRA	CIITA	Clita	Cytosol (Mφ, Tφ, Bφ)	IFN γ

AIM2			Cytosol	DNA

Known PRR, organised as a table on NLR. Paul-Clark MJ, George PM, Gatheral T, Parzych K, Wright WR, Crawford D, Bailey LK, Reed DM, and Mitchell JA (2012) Pharmacology and therapeutic potential of pattern recognition receptors. *Pharmacology & Therapeutics* 135: 200–215.

The last 10–20 years has confirmed a significant phenotypic diversity in tissue macrophages, which directly effects their responses to individual bacteria (Orechioni et al., 2019). While there is still debate over exact definitions the classical or M1 activated macrophage releases huge quantities of proinflammatory cytokines, including TNF α , IL-6, IL-12 and IFN- γ and antibacterial agents such as nitric oxide (NO) and reactive nitrogen species (RNS). They kill bacteria through nitrogen mediated radicals (RNS) produced by inducible nitric oxide synthase (iNOS) following efficient phagocytosis and are potently antibacterial. In contrast, alternative or M2 activated macrophages have enhanced production of anti-inflammatory cytokines IL-4, IL-10 and arginase and have roles in reducing bacteriocidal activity. This is particularly important with respect to bacterial biofilms where *S. aureus* and *P. aeruginosa* induce M2 macrophage activation whereas *E. coli* induces the M1 activation phenotype (Thurlow et al., 2011; Yu et al., 2020a). Macrophages have a life span of weeks and their importance to protect against bacterial infections has been confirmed using macrophage depletion strategies. Here removal of macrophages increases bacterial loads in *P. aeruginosa* (Horino et al., 2009), *Bacillus anthracis* (Cote et al., 2004) and in natural neonatal *Pasteurella pneumotropica* (Saini et al., 2016) infection.

An important note must be addressed with respect to infectious dose. While, unsurprisingly an increase in the number of infectious bacterial cells often leads to increased pathogenesis and tissue damage, it is very important to note that dose is also intricately linked to immune system activation. Low inocula of bacteria, as that associated with nocturnal aspiration into the lungs from the oropharynx, will likely be cleared by macrophages alone. In contrast, higher doses, will require recruitment of blood derived phagocytes and may also stimulate adaptive immunity and the generation of lymphocyte memory to protect against future infections. This point is particularly important when considering the impact of high virulence bacteria (e.g. *S. aureus*, *P. aeruginosa* and *E. coli*) versus low virulence bacteria (*S. epidermidis* and *P. acnes*) that are responsible for chronic low grade infections such as in medical device failure (Lovati et al., 2017).

Epithelial cells

Situated at the interface between the host and the outside world, epithelial cells act as a barrier to protect underlying tissues. They form an integral monolayer held together by tight junctions whose integrity prevents bacterial invasion while at the same time allowing solute absorption. Epithelial cells are not just neutral barriers (see above), but synthetic cellular machines capable of producing molecules essential for host defence against bacteria. Epithelial cells express PRR constitutively, but these can be up-regulated upon stimulation to produce an anti-bacterial shield. Epithelial derived mediators include mucins, antimicrobial peptides and cytokines and chemokines. Epithelial cells have different antibacterial phenotypes based on their anatomy. In the gut epithelial cells are situated adjacent to commensal and pathogenic bacteria continuously. This requires a greater tolerance to activation and damage, while sensing for danger (Peterson and Artis, 2014; Soderholm and Pedicord, 2019; O'Callaghan and Corr, 2019). In the lung, a delicate balance of air-exchange must be maintained against a background of inspired bacterial pathogens (Bissonnette et al., 2020; Whitsett and Alenghat, 2015; Kirkpatrick et al., 2018; Leiva-Juarez et al., 2018). In the skin, multiple layers of epithelial cells form a water permeable seal to retain moisture and respond to bacterial pathogens (Bitschar et al., 2017; Chieosilapatham et al., 2021).

Innate lymphoid cells and NK cells

Recent advances in the understanding of early immune responses to bacteria have also detected PRR on a heterogeneous group of lymphocytes, termed innate lymphoid cells (ILCs) (Montalban-Arques et al., 2018; Beck et al., 2020). While they are derived from lymphoid progenitors, they do not express the T-cell receptor (TcR/CD3) suggesting that they do not participate in major histocompatibility (MHC) restricted detection. They reside in the lamina propria below the epithelial cell monolayer and respond rapidly to infection. To date, three groups have been identified, termed ILC-1, ILC-2 and ILC-3, each having slightly different roles in immunity. Responses to bacteria are mainly associated with ILC-1 and ILC-3 cells in gut and lung. Specifically, IL-22 producing ILC cells appear in the intestine upon *Citrobacter rodentium* infection (Cella et al., 2009) and in response to microbial flora (Satoh-Takayama et al., 2008). Furthermore, this response is essential for protection against *C. rodentium* (Basu et al., 2012; Zheng et al., 2008). ILC 1 and 3 are also essential for protection against human pathogens of the gastrointestinal tract, such as *C. difficile* (Abt et al., 2015) and *S. typhimurium* (Kupz et al., 2013) as well as respiratory pathogens such as *Klebsiella pneumoniae* (Xu et al., 2014) and *Streptococcus pneumoniae* (Van Maele et al., 2014). In contrast, ILC-2 cells generate inflammatory injury induced by *S. aureus* (Hardman et al., 2017).

Innate T cells

While T lymphocytes are commonly associated with adaptive immunity and restricted activation through binding of their $\alpha\beta$ /gamma delta ($\gamma\delta$) T cell receptors (TcR) to MHC class I and II receptors (see T-cells) the "innate T cells" form a heterogeneous collection of three groups expressing high levels of the marker CD161 (Gao and Williams, 2015; Trottein and Paget, 2018; Krovi and Gapin, 2018; Fichtner et al., 2020). These groups include; (i) mucosal associated invariant $\alpha\beta$ -T cells (MAIT), (ii) invariant natural killer $\alpha\beta$ -T cells (iNK) and (iii) $\gamma\delta$ T-cells. Current research suggests that these groups may be separated further but this is beyond the scope of this review. The iNKT, MAIT, and gamma delta ($\gamma\delta$) T cells play an important role in anti-bacterial defence through cytokine production, perforin release, and cross-talk to other innate and adaptive cells. Specifically, iNKT knockout mice succumb to enhanced infection to *Streptococcus pneumoniae* infection, showing increased mortality, higher bacteria load and decreased early neutrophil specific chemokines compared to wild-type mice (Kawakami et al., 2003). Furthermore, recruitment of iNKT to the lung is observed in response to *Chlamydia pneumoniae* infection with the cells recruited being strain specific (Joyee et al., 2007). Consistent with this are studies suggesting that iNKT cells play a protective role against *Salmonella*-induced reactive arthritis (Noto Llana et al., 2017). Likewise, MAIT cells have been shown to increase in response to live *Francisella tularensis* intracellular infections and produce key protective cytokines IFN γ , TNF α and IL-17A (Meierovics et al., 2013). The cytolytic potential of MAIT granular contents is highly regulated with resting states showing low granzyme B and perforin, which are activated upon bacterial stimulation (Kurioka et al., 2015). $\gamma\delta$ T-cells produce important protective cytokines IFN- γ , TNF α and IL-17A, but are also thought to establish long lived "memory" populations essential for the defence against *M. tuberculosis*, *S. aureus*, *B. pertussis*, *L. monocytogenes*, and *Salmonella enterica* (Shepherd and McLaren, 2020; Khairallah et al., 2018).

Targeting and marking bacteria

Soluble PRR (Smole et al., 2020) are structurally quite diverse but share binding properties that allow them to eliminate bacteria in the extracellular space through agglutination and opsonization, complement activation and ultimately phagocytosis (Fig. 3). They are constitutively produced by hepatocytes and immune cells, but are rapidly upregulated by bacterial stimulation and are known to provide specific anti-bacterial defence.

Fig. 3 Protein structures, source and roles of sPRRs in the airways. Shown are the functional structures of pentraxins, collectins, ficolins and SAA proteins and their prominent family members. Local production of pentraxins in the lung could be detected in structural and myeloid cells as well as neutrophils. While the lung (type 2 alveolar cells) is the main synthesis site of the collectins SP-A and SP-D, MBL is primarily produced by the liver. Ficolins are produced in the liver by hepatocytes and in the lung by type 2 alveolar cells, as well as by neutrophils, macrophages and monocytes. SAA proteins, similar to pentraxins, were long thought to be liver-derived serum factors but are also produced locally in the lung by type 2 alveolar cells, macrophages and monocytes. sPRRs share overlapping but also nonredundant roles in the first line of defence against microbial intruders through opsonic activity, inhibition of viral entry and the activation of the complement cascade. Some sPRRs play essential roles in the removal of apoptotic bodies, which is crucial for pulmonary immune tolerance and tissue homeostasis. In addition, several sPRRs are involved in leukocyte recruitment to the lung and local proinflammatory cytokine production. Smole U (2020) Soluble pattern recognition molecules: Guardians and regulators of homeostasis at airway mucosal surfaces. *European Journal of Immunology* 50: 624–642.

The pentraxins (PTX) (Haapasalo and Meri, 2019)

Pentraxins are a superfamily of cyclic multimeric sPRR and include the long pentraxin (PTX-3) (Porte et al., 2019) and the short pentraxins, C-reactive protein (CRP) and Serum amyloid P (SAP). All the pentraxins are intricately involved in complement activation through their opsonizing capacity. However, their anti-bacterial activities remain complex due to binding at multiple levels of the pathway and furthermore an ability to bind activators (e.g. C1q) as well as inhibitors (Factor H). It is clear that PTX-3 has a protective role against bacterial infections, especially to *S. flexneri* (Ciancarella et al., 2018) and uropathogenic *E. coli* (Jaillon et al., 2014). In contrast, CRP was originally named by its ability to bind to the phosphocholine segment of the C-type lectin of pneumococcus in a calcium dependent manner. There is also good evidence to suggest that high CRP levels are associated with bacterial infections and low levels are associated with viral infections (Thomas et al., 2020). Less data exists on SAP, however Yuste and colleagues confirmed that SAP binds to *S. pneumoniae* and activates complement by the classical pathway, improving the phagocytic efficiency (Yuste et al., 2007).

Serum amyloid A (SAA)

Serum amyloid A (SAA) binds to outer membrane protein A (Hari-Dass et al., 2005) and acts as an opsonin for Gram negative bacteria, like *E. coli* and *P. aeruginosa* (Shah et al., 2006). Indeed, recent work suggests that SAA may bind bacterial lipoproteins for delivery and stimulation of TLR-2 (Burgess et al., 2018). Very recent work using a double knockout mouse for SAA1 and 2 confirmed that SAA is essential for protection against *S. aureus* by a mechanisms involving IL-6 (Zheng et al., 2020). Furthermore, it was clear

that its killing action was pH dependent. It is clear that SAA is a retinol binding protein needed for defence against *S. typhimurium* *in vivo* (Derebe et al., 2014) and *K. pneumoniae* *in vitro* (Zheng et al., 2016). However, while physiologically relevant concentrations of SAA seem to have little effect on urinary pathogenic *E. coli* (UPEC), they do seem to inhibit biofilm formation (Erman et al., 2012).

Collectins: Mannan binding lectin (MBL) (Beltrame et al., 2015) and surfactant proteins A and D (Kuroki et al., 2007)

Collectins are collagen containing C-type lectins and play important specific roles in anti-bacterial defence and include mannose-binding lectin (MBL) and surfactant protein A (SP-A) and SP-B. Specifically, SP-A has been shown to opsonise *S. aureus* for uptake by macrophages. In contrast, SP-D opsonises Gram negative bacteria including *E. coli* and activates respiratory burst in macrophages and uptake by dendritic cells. Mice deficient in SP-A and SP-D support unique roles for each molecule. SP-A is required for appropriate protective defence against group B streptococcus infection (LeVine et al., 1997, 1999) and *P. aeruginosa* infection (LeVine et al., 1998). The same author compared group B streptococcus infection and *H. influenzae* infection in both SP-A and SP-D deficient mice and found that SP-A, but not SP-D, was associated with increased bacterial killing (LeVine et al., 2000) despite both molecules playing a role in inflammation. MBL monomers self-associate to form trimers which provide the correct conformation for MBL-associated serine protease (MASP) to activate the complement cascade through the lectin pathway. MASP-2 deficient mice have poor defence against *S. pneumoniae* due to a failure in opsonization (Ali et al., 2012) but do not play a role in *P. aeruginosa* infection (Kenawy et al., 2012).

Ficolins (Bidula et al., 2019)

Ficolins represent a class of opsonins that are characterized by the presence of a C-terminal fibrinogen-like and an N-terminal collagen-like domain (fi-col-ins) that have distinct ligand specificities (GlcNAc GalNAc, sialic acid, D-fucose). All 3 types, M-, L-, and H-ficolin (also termed Ficolin-1, -2 and -3 respectively) interact with bacteria by primarily acting as opsonins. However, they can also activate the lectin pathway. L-ficolin (ficolin 2) is by far the best studied and it is clear that it has a diverse binding capability that provides protection against numerous bacteria, including *M. tuberculosis* (Kobayashi et al., 2019), enteroaggregative *E. coli* (Adler Sorensen et al., 2018), *M. leprae* (de Messias-Reason et al., 2009) and *S. pneumoniae* (Endo et al., 2012). Indeed one important general mechanism that might be employed here is through natural antibody (not antigen induced) binding to ficolin-opsonised bacteria (Panda et al., 2013). Furthermore, bacterial infections associated with immunocompromised patients, including diabetes mellitus, primary immunodeficiencies, liver cirrhosis and B cell leukemia may be due to polymorphisms in ficolin genes (Barkai et al., 2019; Babaha et al., 2020; Foldi et al., 2017; Pana et al., 2014).

Complement

Paul Ehrlich described the heat-labile activity of the soluble fraction of blood as complement as it supported the activity of the cellular leukocyte fraction (Kaufmann, 2008). Today we understand complement as a protein zymogen cascade where members are cleaved for system activation. It has been termed the guardian of the extracellular space (Heesterbeek et al., 2018). Complement has three major pathways and three major downstream functions to clearing bacteria. Critically complement is essential for immunity to extracellular phases of bacterial infection and moreover it is required for the killing of Gram-negative bacteria. In particular, *Neisseria meningitidis* are sensitive to these effects. In contrast, the much thicker layer of peptidoglycan and specific evasion mechanisms are thought to provide complement resistance in Gram positive organisms such as *S. aureus* despite an ability of complement to deposit on their surfaces (Berends et al., 2013). Interestingly however, it is clear that the distinction may be slightly more complicated as *E. coli* pathotypes have unique sensitivities to complement, including extraintestinal strains showing strong serum resistance (Miajlovic and Smith, 2014).

Immunoglobulin (antibody) (Hey, 2015)

Immunoglobulins provide protection against extracellular bacterial infection through a variety of routes. Their specific and avid binding to target bacteria provide, an early signpost for six different mechanisms of killing once antibody has bound (Fig. 4); (i) complement activation (by classical pathway) and complement dependent cellular cytotoxicity (CDCC) through MAC formation; (ii) activation of ILC-1 cells (NK cells) through Fc receptors to deliver cellular lysis through antibody dependent cellular cytotoxicity (ADCC); (iii) binding and neutralization of bacterial toxins; (iv) opsonization of bacteria for antibody dependent phagocytosis; (v) degranulation of granulocytes (e.g. neutrophils and mast cells) through receptor aggregation following antibody crosslinking (Menon et al., 1986); (vi) agglutination of bacteria though antibody crosslinking and complex formation restricts bacterial adhesion and invasion.

The importance of antibody in the immune response to bacterial infections is confirmed in the X-recessive primary immunodeficiency agammaglobinaemia, where patients have severely reduced numbers of peripheral B-cells (less than 2% of normal), severely reduced serum immunoglobulin levels of all classes, and a lack of a humoral response to antigens (Bousfiha et al., 2018; Bruton, 1952). A recent long-term follow-up in 168 patients confirmed bacterial infections in the skin, respiratory and

Fig. 4 A summary of the protective functions of antibody. (1) Antibodies bind to pathogen-derived or endogenous antigens expressed on the surface of an infected cell, which triggers binding to Fc receptors on natural killer cells and lysis of the infected cell by antibody-dependent cellular cytotoxicity. (2) Antibodies bind to pathogen-derived or endogenous antigens expressed on the surface of infected cells, which triggers activation of complement through binding of complement factor C1q. (3) Neutralization, here a bacterial toxin neutralized by bound antigen. (4) Antibody bound to bacterial surface proteins binds to Fc receptors on phagocytic cells, e.g., macrophages, and triggers endocytosis and destruction of bacteria in endolysosome; (5) Antibody binding to bacterial antigen can trigger the degranulation of neutrophils and mast cells by Fc receptors; (6) Agglutination of bacteria through antibody crosslinking. Antibacterial functions of antibodies. Hey A (2015) History and practice: Antibodies in infectious diseases. *Microbiology Spectrum* 3: AID-0026-2014.

gastrointestinal tracts (Lougaris et al., 2020). In most cases bacteria were encapsulated species with a significant proportion of their pathogenesis spent in the extracellular space confirming the importance of antibody in this tissue space. The most frequently isolated pathogen in the skin was *S. aureus* (~75%), in the lung *Haemophilus influenzae* and *Streptococcus pneumoniae* (53 and 18% respectively) and in the gut *Salmonella* (24%), *Campylobacter* (19%), and *E. coli* (5%).

Responding to bacteria and recruiting appropriate cells

Neutrophils are short lived blood phagocytes that are recruited to the sites of infection to phagocytose and kill extracellular bacteria. They are almost essential for protection against extracellular phases of infection as demonstrated by chronic granulomatous disease (CGD) (Yu et al., 2020b). This is a very rare primary immunodeficiency (~1 in 250,000) where patient suffer from recurrent bacterial (and fungal) infections in areas patrolled by neutrophils including the lungs, lymph nodes, skin, liver and bones. Specifically, infections are associated with catalase positive bacteria including *S. aureus*, *Burkholderia cepacia* complex, *Serratia marcescens* and *Nocardia species*, but extend to others including *P. aeruginosa*, *K. pneumoniae*, *E. coli* and *Salmonella species*.

Neutrophils and the CXCL2-CXCR2 axis

Both CXCL1 and CXCL2 act through CXCR2 expressed on neutrophils. Antibody neutralization of CXCR2 has confirmed the need for neutrophil recruitment in models of *P. aeruginosa* (Tsai et al., 2000). Consistent with this, CXCR2 deficient mice have severely perturbed recruitment of neutrophils (and exudate macrophages) resulting in bacterial outgrowth in pneumococcal pneumonia (Herbold et al., 2010).

Monocyte recruitment and the CCL2-CCR2 axis (Serbina et al., 2008; Shi and Pamer, 2011) and mononuclear phagocyte system

Monocytes are important for providing a major source of macrophages and dendritic cells in peripheral tissues. At least two distinct subsets can be distinguished in humans and mice that are responsible for constitutive macrophage production and recruitment during infection respectively (Shi and Pamer, 2011). Inflammatory monocytes are extremely important for immune defence against certain bacterial infections. Indeed *L. monocytogenes* is even named for the observation that part of its pathology is the accumulation

of monocytes in peripheral tissues. Transgenic mice overexpressing CCL2 in epithelial cells have improved bacterial clearance and mortality following pneumococcal (Winter et al., 2007) and *M. bovis* (Schreiber et al., 2008) challenge compared to their wild-type counterparts. In the same pneumococcal infection model CCL2 knockout mice had greater lung burden and sepsis than their wild-type counterparts and this was due to numbers of recruited monocytes and dendritic cells (Winter et al., 2009). Consistent with this were results in a neonatal *E. coli* pneumonia model where CCR2 deficient mice had increased mortality compared to their wild-type controls (McGrath-Morrow et al., 2017). Similarly, *L. monocytogenes* infection cannot be cleared in CCR2 deficient mice because of defective monocyte recruitment (Kurihara et al., 1997).

Cytokines responsible for host resistance to bacterial infections have been identified in knockout mice and in human disease (Netea et al., 2004)

Cytokines provide essential intercellular signaling between immune cells during a bacterial infection. Their efficacy to activate the correct immune program, to provide appropriate immunity for a given bacteria is central to their importance. They may be grouped by structure, by function, by their importance to innate or adaptive immunity or by their cellular source, however in this review, focus will be made to their requirement for defence against specific bacterial infections. Specifically, the major pro-inflammatory cytokines IL-1 β , IFN- γ , TNF α , IL-12 and IL-18 have been shown to be critical to defence against a variety of bacterial infections. IL-1 β is needed for optimal neutrophil dependent control of infection (Mayer-Barber and Yan, 2017). Similarly, early work in TNF receptor deficient mice confirmed that they were protected from lethal doses of toxins such as LPS and staphylococcal enterotoxin, but died following *L. monocytogenes* infection (Pfeffer et al., 1993). Indeed the importance of IL-1 β and TNF α is underlined in treatment of Crohn's disease and arthritis with anti-TNF monoclonal antibodies (infliximab) and IL-1 receptor antagonists (anakinra), where therapy can induce a state of secondary bacterial infection (Salliot et al., 2009; Keane et al., 2001; Fernandez-Ruiz and Aguado, 2018). IFN- γ has specific activities to "acidify" the phagolysosome within infected macrophages. This activity combined with enhancing reactive nitrogen species and the induction of autophagy allows IFN- γ to increase macrophage bactericidal capabilities. IFN- γ is important for defence against *M. tuberculosis*, *S. typhimurium* and *L. monocytogenes* (Kak et al., 2018).

IL-12 (and its family member IL-23) and IL-18 are major IFN- γ inducing cytokines and many of their effects can be abolished in the absence of IFN- γ (Flynn et al., 1995). Indeed, mutations in genes of the IL-12/IFN- γ axis are responsible for increased susceptibility to *M. tuberculosis* and *Salmonella* infections (Ramirez-Alejo and Santos-Argumedo, 2014). As such, they have clearly overlapping activities with IFN- γ and protect against bacterial infections such as *L. monocytogenes*, *Y. pestis* and *S. typhimurium*. IL-18 seems to have a broader spectrum showing protection against *S. aureus* (Wei et al., 1999), *S. pneumoniae* (Lauw et al., 2002), and *P. aeruginosa* (Huang et al., 2002).

IL-17 (and its family members IL-21 and IL-22 (Koenders and van den Berg, 2010)) is the guardian of the mucosal barriers (Cypowyj et al., 2012). It is required for protection in a variety of mucosal infections including lung infections caused by *Klebsiella pneumoniae*, *Bacillus anthracis*, and *Mycobacterium bovis* BCG, oral infections to *Porphyromonas gingivalis*; gastric immunity to *Helicobacter pylori*; urogenital immunity to *Neisseria gonorrhoeae*; intestinal immunity to polymicrobial sepsis; cutaneous skin immunity to *S. aureus*.

IL-10 is the prototype anti-inflammatory cytokine, responsible for inhibiting the early proinflammatory responses to stimulate tissue homeostasis (Penaloza et al., 2016). This regulatory activity has huge implications in bacterial infections. Recent hypotheses on the functions of IL-10 suggest that it is required to limit inflammation in response to extracellular bacteria like *S. pneumoniae* and *P. aeruginosa* and highly pro-inflammatory intracellular bacteria like *M. tuberculosis*, *E. coli* and *F. tularensis*. This would allow bacterial clearance without tissue damage and bacterial dissemination. In contrast, excessive IL-10 suppression of the immune response can allow intracellular bacteria like *L. monocytogenes*, *B. abortus* and *S. enterica*, to survive and disseminate but critically could also allow commensal bacteria to survive in the host.

Finally, it is very clear that the cytokine system is based on a significant amount of biological redundancy. The ability to substitute and overlap biological activities is a strength in generating appropriate immunity to bacteria. While the number of interactions here is almost limitless, much can be learned from studies in mice deficient in cytokine signaling molecules (Matsukawa, 2007), but also in polymorphisms associated with cytokines and their receptors that produce susceptibility to infectious disease (van Deventer, 2000; Smith and Humphries, 2009).

Generating a bespoke specific immune response (Boes et al., 2009; Gatfield et al., 2000; Ramachandra et al., 1999a, b; Watts, 2004)

Production of specific immunity and memory toward a given bacterial pathogen requires the "processing" and "presentation" of parts of its structure in the form of peptides or lipids on the surface of host cells through the major histocompatibility complex (MHC) and CD1 receptors. Distinctions can be made on how bacteria are managed. Extracellular bacteria are phagocytosed by macrophages and dendritic cells, with bacterial antigens entering the endosomal-lysosomal pathway for surface presentation on MHC-class 2 molecules. Binding of the correct T-helper cell (CD4 positive) to this MHC with co-stimulatory molecules activates immune mechanisms targeting the extracellular environment through the production of appropriate cytokines. Intracellular or

cytosolic bacteria identified in any other nucleated cells are degraded by the cytosolic proteolytic machinery, and proteasome for transport to the endoplasmic reticulum and cell surface presentation on MHC-class 1 molecules. Binding of the correct cytotoxic T-lymphocyte (CD8 positive) and co-stimulatory molecules alerts that lymphocyte toward the infected cells resulting in induction of apoptosis or cell lysis. These pathways have resulted in a clear understanding of adaptive immunity to a variety of pathogens and the diversity in their responses.

With respect to bacteria that have largely extracellular lifestyles. *S. aureus* induces a protective Th2 response in the skin associated with increased phagocytic neutrophils (Nippe et al., 2011). This is related to induction of epithelial derived Th2 cytokines such as IL-5 and IL-13 (Lan et al., 2018). In contrast, *S. epidermidis* induced no Th2 cytokines (Lan et al., 2018) but has shown strong Th17 protective immunity in the skin (Naik et al., 2015). *Campylobacter* has demonstrated robust Th1 immunity (Rathinam et al., 2008) which changes with time from Th1 to Th2 response while assessing for the related neurological syndrome Guillain Barre (Nyati et al., 2012). Furthermore, *Campylobacter* infection in chickens has also been associated with a Th17 response (Reid et al., 2016). *S. pneumoniae* induces Th1 and Th17 responses to experimental infection (Kim et al., 2013a; Olliver et al., 2011) and a similar response to attenuated vaccination (Gao et al., 2016; Zhang et al., 2017; Qiu et al., 2017). *S. pyogenes* induces a Th1 response (Agren et al., 1998). Furthermore, parenteral administration of an anti-GAS vaccine was able to protect against intranasal inoculation through Th17 immunity involving specific IgA induction (Mortensen et al., 2017). *Haemophilus influenzae* generates a Th1 response (Agren et al., 1998). However, comparative vaccination by a variety of routes, including nasal, oral, tracheal or peritoneal confirmed that the nasal route provided the best protection against an intranasal challenge through a Th1 and Th2 response with local IgA and systemic IgG protection (Kurono et al., 1999). Consistent with this, conjugate vaccines, such as Hib-CRM(197) also generated a mixed Th1 and Th2 response and vigorous T-cell memory (Kamboj et al., 2001). *E. coli* heat-labile enterotoxin induces strong Th17 responses in experimental models through IL-1 β and IL-23 (Brereton et al., 2011). This response has been applied to vaccines which generate IgG2a and IgA responses (Norton et al., 2012) to enterotoxins. Similar responses have been observed to *E. coli* outer membrane proteins (OMP) which also share Th1/Th17 immunity, although protection is offered by T cells (Kim et al., 2013b). Indeed, consistent Th1/Th17 responses or also observed to uropathogenic *E. coli* pathotypes (Quick et al., 2013).

With respect to bacteria that have a high proportion of intracellular lifestyle. For *S. typhimurium* MHC-class 1 knockouts show increased susceptibility to infection and increased CD8 positive T-cells can be detected (Lo et al., 1999). Vaccination studies using non-lethal Aro mutants of *Salmonella* show increased survival in IFN- γ knockout mice. Wild type mice have increased CD4 and CD8 specific cells (Bao et al., 2000). Furthermore, vaccines to *S. typhimurium* in humans generate Th1 cytokines, including IFN- γ and TNF α . This results in classical MHC class Ia-restricted responses and novel, nonclassical MHC class Ib-restricted CD8(+) cytotoxic T cell responses (Sztein, 2007). Other species of *Salmonella* differ slightly. Vaccination of pigs against *S. choleraesuis* using C500, induces mucosal IgA and CD8 immunity (Zhu et al., 2017). In contrast *S. enteritidis* infection depends on strong early IL-12 production to reduce infected neutrophils and generate CD4 and CD8 specific responses (Lehmann et al., 2001). Adaptive immunity to *L. monocytogenes* as a facultative intracellular pathogen requires IL-12 induced CD4+ Th1 immunity (Hsieh et al., 1993). Indeed this IL-12 dependent response is so strong that heat-killed *Listeria* can convert established Th2 immunity (characterized by high specific IgE) into Th1 immunity (characterized by high IgG, IFN- γ and low IL-4) (Yeung et al., 1998). However, these effects are subject to local tissue differences in the liver, spleen and mucosal tissues (Marzo et al., 2002; Kuranaga et al., 2005) and the Th1 response is also dependent on the atypical NF κ B inhibitor I κ BNS (Frentzel et al., 2019). There is very good evidence that *M. tuberculosis* responses are dominated by CD4+ Th1 cytokines like IFN- γ (Robinson et al., 1994). Consistent with this is that successful antimycobacterial therapy also induces Th1 immunity (Marchant et al., 2001). Pathogenesis requires lymphocytes as severe combined immunodeficient (SCID) mice succumb to infection and virulent strains of *M. tuberculosis* are successful because they subtly suppress Th1 immunity (Manca et al., 2001). Indeed, in African countries poor outcomes are observed due to a reduced Th1/Th2 ratio (Lienhardt et al., 2002) potentially due to endemic helminth infections (Amelio et al., 2017). Finally, *Chlamydia trachomatis* generates Th1 immunity and IFN- γ is critical in combination with CD4+ immunity (Marks et al., 2007; Gondek et al., 2009). However, the situation is complicated by anatomical segregation in the genital tract where Th1 immunity dominates in the upper genital tract but Th2 immunity in the lower genital tract (Marks et al., 2010). This is consistent with recent findings of both phenotypes in women with *C. trachomatis* infection (Ogendi et al., 2018).

Body compartments-local mucosal and systemic responses

Mucosal associated lymphoid tissue (MALT)

On a macroscopic scale it is clear that immune responses to bacteria are anatomically specific, despite a great degree of overlap in the cellular mechanisms and soluble mediators. Body sites that are at an interface with the external environment have their own specialized local combined innate and adaptive immune mechanisms to sample and respond to bacteria. These collections of cells are termed mucosal-associated lymphoid tissue (MALT). Recent reviews provide important information on the differences at each site including iSALT (Chen et al., 2018; Belkaid and Tamoutounour, 2016; Honda and Kabashima, 2016), NALT (Pabst, 2015; Takaki et al., 2018), BALT (Randall, 2010; Foo and Phipps, 2010), GALT (Morbe et al., 2021), and vaginal mucosal host defence (Smith and Ravel, 2017; Cole, 2006) are provided elsewhere in this book.

Blood

In normal health, the blood compartment is sterile, with limited numbers of bacteria. However, surgery, intravenous catheters or highly virulent invasive bacteria can reach the blood compartment. Numerous mechanisms exist for protecting this vital compartment from bacterial infection. The systemic effects of bacterial PRR activation are often termed the acute phase response, which is a systemic immune response program of events. These include (i) fever and hyperalgesia; (ii) release of acute phase proteins by the liver; (iii) vasodilation of blood vessels; and (iv) recruitment of leukocytes from the blood (Slaats et al., 2016). The resident liver macrophage, termed a Kupffer cell, clear bacteria from the circulation through the complement receptor of the immunoglobulin family CRIg, through binding the opsonin molecules C3b and iC3b (Helmy et al., 2006). Recently, it has been suggested that clearance of bacteria from the blood compartment is a dual process involving parallel “slow” and “fast” mechanisms of clearance (Broadley et al., 2016). “Slow clearance” involves bacterial opsonization, platelet binding, and capture of bacteria-platelet-complexes via the complement receptor of the immunoglobulin superfamily, CRIg. “Fast clearance” involves uptake and destruction in the liver via Kupffer cell scavenger receptors. This dual mechanism is important as the “slow clearance” spares some bacteria for adaptive immunity induction by splenic CD8a+ dendritic cells. Indeed, it is clear that this small portion of bacteria associated with platelets are dependent on glycoprotein, GPIb and complement C3, diverting them to splenic dendritic cells to generation of longer-term immunity (Verschoor et al., 2011).

Differentiating bacterial pathogens and commensals

The state of homeostasis active in health is in a state of continuous antigenic challenge and flux. The best example of this is in the gut where continuous monitoring is essential to maintain barrier integrity (Fig. 5). However, what mechanisms are in place to allow the immune system to differentiate between a bacterial commensal and pathogen? Recent research has identified hundreds of potential mechanisms, which have been organized here with a few relevant examples and broader reference to appropriate manuscripts (Sassone-Corsi and Raffatellu, 2015; Sun et al., 2015) :

Commensals enhance epithelial barrier function

There is a clear link between the production of functional two layer intestinal mucus by specific PAMPs such as LPS or commensal bacteria (Petersson et al., 2011). It is also well known that *Bifidobacterium infantis* (90% of the microbiota in healthy infants) secretes bioactive factors that improves epithelial barrier integrity (Ewaschuk et al., 2008). In addition, *Bifidobacterium* has been shown to protect against enteropathogenic infection through the production of short-chain fatty acids (SCFA), such as acetate (Fukuda et al., 2011) through carbohydrate transporter molecules (Fukuda et al., 2012).

Commensals enhance innate immunity

Commensal bacteria are required for Paneth cell secretion of the antimicrobial C-type lectins REG3 γ and REG3 β through a TLR mediated MyD88 pathway. Consistent with this is the ability of enteric bacteria to activate a Paneth cell transcriptional panel of antimicrobial factors, including REG3 β , REG3 γ , CRP-ductin, which agglutinates Gram-positive and Gram-negative bacteria; the inflammatory modulator resistin-like molecule- β (RELM- β); and several members of the α -defensin family of antimicrobial peptides (Vaishnava et al., 2008). Under normal circumstances commensal bacteria generate poor pro-inflammatory responses, however in the presence of pathogens a regulated pro-inflammatory response is generated through targeting the processing of IL-1 β and IL-18 (Hasegawa et al., 2012). Consistent with this is work implicating the NLRC4-inflammasome in processing IL-1 β signals to differentiate commensal and pathogens (Franchi et al., 2012). Thus commensal organisms produce unprocessed proinflammatory signals, whereas pathogens appear to provide the necessary extra signals from production of mature pro-inflammatory cytokines.

Commensals enhance of adaptive immunity

It is clear that some commensal bacteria have the ability to drive the differentiation of specific T-cell clones. Early, work confirmed that dendritic cells could use “snorkeling” mechanisms to sample luminal bacteria prior to migration to lymph nodes to activate a specialized transcriptional program for T-regulatory cells (Rescigno et al., 2001) following induction by TLR ligands (Chieppa et al., 2006). Indeed, T cells primed by DCs activated by commensals express integrin α 4 β 7 and CCR9 and home to the gut where they generate tolerogenic responses to commensals (Iwata et al., 2004). This response requires retinoic acid for full T-cell homing. In contrast, the Clostridiales family of segmented filamentous bacteria (SFB), specifically induce the differentiation of mucosal Th17 cells in the lamina propria of the intestine, which, in turn, secrete the proinflammatory cytokines IL-17 and IL-22 which enhance antimicrobial peptide generation (Ivanov et al., 2009). In impressive state of the art experimentation, members of the family Clostridia were isolated from healthy human feces based on their ability to induce CD4+FOXP3+ regulatory T-cells promoting TGF β and IL-10 production. Critically these strains were shown to reverse pathological colitis (Atarashi et al., 2013). In the skin, commensal *S. epidermidis* are critical in generating protective Th17+CD8+ T cells that home to the skin generating immunity to protect against pathogen invasion (Naik et al., 2015). Equally important mechanisms exist for B-cells. Indeed, dendritic cells

Fig. 5 Microbiota-stimulated host immunity provides colonization resistance. Commensal bacteria can indirectly control pathogen colonization by a variety of means. (1) Barrier function: the commensal microbiota upregulate host barrier function by contributing to the development of the mucus layer. (2) SCFA production: members of the microbiota, such as *Bifidobacterium* spp., can enhance epithelial barrier function by producing SCFAs, such as acetate. (3) IL-1 β -mediated neutrophil recruitment: commensals can promote protection against certain pathogens by stimulating IL-1 β processing and secretion, resulting in the recruitment of neutrophils to the site of the infection. (4) IL-22-dependent release of antimicrobials: certain commensals (such as *L. reuteri*) induce the secretion of IL-22 by ILCs, which, in turn, can protect against some pathogens via the induction of antimicrobial release by epithelial cells. (5) Direct stimulation of antimicrobial production by the host: secretion of antimicrobial proteins (AMPs), including α -defensins and REG3 γ , is a key component in controlling pathogen growth and is mediated, in part, by commensal-dependent mechanisms. (6) Induction of T cell differentiation: commensals can promote adaptive immunity by inducing the differentiation of T cells, such as by stimulating Th17 cell and Treg differentiation and activation. (7) sIgA: commensals can facilitate host-barrier function by inducing B cells and by regulating the secretion of IgA. Differentiating pathogens and commensals. Sassone-Corsi M and Raffatellu M (2015) No vacancy: How beneficial microbes cooperate with immunity to provide colonization resistance to pathogens. *Journal of Immunology* 194: 4081–4087.

containing low levels of commensal microbes (e.g. *Enterobacter cloacae*) can selectively generate IgA to protect the host from its own microbiota (Macpherson and Uhr, 2004). Indeed, SFB, but not commensal *E. coli*, were shown to contribute to the development of intestinal lymphoid tissue, including Peyer's patches, and to the development of intestinal sIgA boosting intestinal defence. The authors suggest that SFB have a remarkable capacity to induce and stimulate multiple types of intestinal lymphoid tissues that cooperate to generate potent IgA and Th17 cell responses displaying only limited target specificity (Lecuyer et al., 2014).

Commensals induce subtle changes in cytokine networks

The ability of *Lactobacillus reuteri* to metabolize tryptophan to indole-3-aldehyde, which activates the aryl hydrocarbon receptor (Ahr) on ILC to induce the barrier protective cytokine IL-22. Indeed, it is now clear that the Ahr is important in providing a docking site for microbiota derived ligands for activation of the immune system (Bock, 2020). Studies with probiotic strains of bacteria like *E. coli* Nissle have shown its ability to change the direction of immune responses from Th2 to Th1 protective immunity (Bickert et al., 2009). In the last decade thymic stromal lymphopoietin (TSLP) has been shown to be induced by intestinal bacteria and is important for controlling inappropriate Th17 responses through the maturation of FOXP3 T-regulatory cells (Mosconi et al., 2013).

Conclusions

It is clear that the immune system has evolved a variety of mechanisms to detect, mark, kill and remove bacteria. Our knowledge of the balance and individualized immune responses to different bacteria has advanced by a greater understanding of the host pathogen interactions within the gut (Fig. 6; Sun et al., 2015). Here the three lines of defence, including barriers, innate and adaptive immunity combine to provide subtle variations that allow discrimination between bacteria. Variations on these mechanisms are present at different body compartments (e.g. lung, skin), in different cellular compartments (intra or extracellular), and with dramatic differences in virulence potential. Understanding this network of events is important to understanding bacterial infection processes, but is essential for the design of effective strategies to protect the host from pathogenic bacteria (Blander et al., 2017; Kamada et al., 2013; Chu and Mazmanian, 2013; Brown et al., 2013; Goldszmid and Trinchieri, 2012).

Fig. 6 Microbiota and immune regulatory cells in gut. Schematic shows the location of immune regulatory cells and other immune cells and their signaling cascades in the lamina propria of gut. The luminal microbiome lies adjacent to the intestinal epithelium. The microbiota plays an important role in the maintenance of mucosa homeostasis. Breach of the tolerance leads to the development of inflammatory bowel diseases (IBD), inflammation, and tumor. Intestinal epithelial barrier is the first line of defense to prevent the pathogens invasion, including the epithelial tight junction complexes, mucus layer secretion by goblet cell, secretory immunoglobulin A (sIgA), antimicrobial protein (AMP) secretion by plasma cells, and Paneth cells. With regard to the innate immune response in intestine, neutrophils could be earlier recruited to inflammatory sites to clear the pathogens. In addition, macrophages, dendritic cells (DCs), and innate lymphoid cells (ILCs) could sense antigens and then secrete cytokines or chemokines to regulate the inflammatory responses. Some innate immune regulatory cells such as M2 induced by interleukin (IL)-4 and IL-13 could directly inhibit effector T cells through IL-10 secretion and promote regulatory T cell (Treg) suppressive function by producing transforming growth factor- β (TGF- β). CD103⁺ DCs could regulate intestinal inflammation via facilitating Treg differentiation in a TGF- β - and retinoic acid (RA)-dependent manner. ILC3 serve as an antigen-presenting cell (APC) that uniquely restrain the CD4⁺ T-cell response in a major histocompatibility complex (MHC) II-dependent manner, and could secrete IL-22 that participates in the repair of impaired epithelium. In response to epithelium-derived IL-25 and IL-33, ILC2 could produce IL-5 and IL-13 to play the role of anti-helminth. The primarily regulatory cells are Tregs that suppress effector T-cell differentiation and proliferation by producing IL-10 and TGF- β or expressing CD152. The IL-10-producing type 1 regulatory T (Tr1) cells perform the anti-inflammatory function. Moreover, T helper type 3 (Th3) cells, regulatory B cells (Bregs), and intraepithelial lymphocytes (IELs) have the capacity of suppressing the excessive Th1 and Th17 responses through IL-10 and TGF- β production. Therefore, these immune regulatory cells collectively maintain the intestinal homeostasis by interacting with each other. Cellular and cytokine networks responsible for the immune response to bacteria. Immune system

The immune system is a tightly regulated, complex system of tissues and cellular components (immune cells, lymph nodes and mucosal tissues), and humoral components (antibody, antimicrobial proteins, and complement proteins), that have evolved to work in unison to protect us from infectious diseases. The immune system can also be broken down into innate immunity and adaptive immunity. The innate immune system is a rapid non specific response that helps the body prevent infection from pathogens never encountered before, prior to an antibody response being developed. The adaptive immune system is a slower more pathogen specific response (B cells/T cells). In this chapter we will discuss the above components of the immune system in relation to viral infections. Specifically, how we recognise and respond to viral infections, and ways in which viruses have evolved to try to avoid the host immune system.

Innate immunity - First line of host defense

Before we progress to the key components of the immune system we will first look at the initial barriers that viruses must cross in order to initiate infection, and ways in which the body tries to counteract this. The main routes of pathogen entry into the body are via the mucosal surfaces and the skin.

The skin

The skin, the largest organ of the body, is a very strong physical barrier, that many pathogens find impenetrable. Alongside the physical barrier, the skin is also inhospitable to many pathogens, containing antimicrobial peptides that can kill pathogens (Handfield et al., 2018). It is also covered in commensal skin flora that promote wound healing and restrict the growth of other microbes (Robinson and Pfeiffer, 2014).

Despite this many viruses utilise this as a route of entry into the host, discussed in detail in Bomsel and Alfsen (2003) and Lei et al. (2020). This includes as examples, Human papilloma viruses (HPV) and Herpes Simplex viruses (HSV). Although these infect via the skin an abrasion of some sort is required for viral entry into the body and for infection to occur. Other viruses bypass the skin barrier by transmitting via vectors, that again penetrate the skin barrier. Some examples of common vectors include Mosquitos, Ticks, Fleas, Sandflies. With mosquitos being a common vector aiding transmission of many human viruses, such as Zika virus, Dengue fever virus (DENV), Yellow Fever virus (YFV) and Chikungunya virus (Onyango et al., 2020).

Mucosal surfaces

Other key entry points for viruses and other pathogens into the body include the mucosal surfaces (Bomsel and Alfsen, 2003). This includes the mouth, nose, eyes, respiratory tract, gastrointestinal tract, urinary tract and reproductive tract. With the respiratory and gastrointestinal tract being the main sites of viral entry. All these sites have an arsenal of antimicrobial agents, specialist cells types, mucosal antibody (mainly secretory IgA) and some have inhospitable conditions (low pH). Further they are resident to an array of immune cells that patrol these entry points to prevent pathogen invasion and infection. Some of which we will discuss briefly here in relation to viral infections and are reviewed in Sato and Kiyono (2012) and Holmgren and Czerkinsky (2005).

One clear example of how viruses are able to manipulate these mucosal sites to aid infection and transmission, is seen during infection of the respiratory epithelium by respiratory viruses. The respiratory tract is lined by specialised cell types, mainly the ciliated epithelial and goblet cells, both key for the proper functioning of the mucociliary escalator (Kilburn, 1968; Tam et al., 2011). Ciliated airway epithelial cells (AECs) line the vast majority of the respiratory epithelium and beat in a coordinated directional manner to remove mucus from the airways. This mucus, produced by goblet cells, lines the epithelium and traps pathogens and other inhaled particulates, which is then removed from the airways by ciliated AECs (Jeffery, 1983). Malfunctioning of these cells and the mucociliary escalator, like that seen in conditions such as cystic fibrosis and primary ciliary dyskinesia, results in chronic respiratory infections and lung damage (Wijers et al., 2017; Afzelius, 1976; Boucher, 2007).

The functioning of the mucociliary escalator can also be temporarily damaged due to infection (Pittet et al., 2010). Either through generalised damage to the respiratory epithelium as seen during Influenza virus infection (Plotkowski et al., 1986; Nugent and Pesanti, 1983; Short et al., 2014), or by targeted infection of the ciliated epithelial cells. The latter is a feature seen for many of the common respiratory viruses, such as Respiratory Syncytial Virus (RSV), Rhinovirus (RV) C and some of the Severe Acute Respiratory Syndrome associated Coronaviruses (SARS-CoV). RSV has been shown to specifically targets the ciliated AECs, causing ciliary loss (shedding) and ciliary dyskinesia (uncoordinated movement of the ciliated cells) (Zhang et al., 2002; Smith et al., 2014). The most recently discovered RV species, RVC, has also been shown to target the ciliated epithelium for viral entry and infection leads to shedding of the infected cells, reducing the number of ciliated cells present within the epithelium (Griggs et al., 2017). The receptor used for SARS-CoV infection, angiotensin-converting enzyme 2 (ACE2), has also been shown to be preferentially expressed on ciliated AECs, and targeted infection of these cells causes cell death and shedding into the airway (Li et al., 2003; Sims et al., 2005). Due to the fact SARS-CoV-2 also used ACE2 as its receptor, the viral cause of the 2019 global pandemic, this virus has also been shown to target ciliated cells for infection (Ahn et al., 2021; Zhu et al., 2020). Studies have similarly shown this leads to damage to the ciliated cells and cell shedding into the lower airways, and has been shown to perturb mucociliary clearance (Robinot et al., 2021). Some strains of Influenza A virus (IAV) also show a tropism for ciliated cells (Ibricevic et al., 2006).

Other routes of viral entry into the host and examples of viruses that utilise these routes are summarised in Table 1.

Table 1 Examples of viral pathogens that utilize different entry routes into the host.

Entry route	Viruses
Mouth, Nose, Eyes	RV, Ebola virus (EBOV), Cytomegalovirus (CMV), Epstein-Barr Virus (EBV)
Respiratory tract	IAV, SARS-CoV, SARS-CoV-2, RSV, RV
Gastrointestinal tract	Norovirus, Rotavirus
Urinary tract	Uncommon in immunocompetent hosts
Reproductive tract	Human immunodeficiency virus (HIV), Hepatitis C virus (HCV), EBOV, CMV
Skin	Abrasion – Human papilloma virus (HPV), Herpes Simplex virus (HSV), EBOV, HIV Vector – Zika virus, YFV, DENV

Innate immunity - viral recognition

Once these barriers are breached pathogens are detected by epithelial cells, patrolling immune cells, or antibody, which initiate an immune response to aid pathogen clearance.

Pattern recognition receptors (PRRs)

Key component of the innate immune system are pattern recognition receptors (PRRs). These are present on the cell surface of a number of different cell types (immune cells, epithelial cells, endothelial cells etc), and recognise components shared by many pathogens, which are not present in the host, distinguishing self from non self (Janeway, 1989, 2013; Takeuchi and Akira, 2010). These are known as Pathogen Associated Molecular Patterns (PAMPs). PAMPs include things such as lipopolysaccharide (LPS), flagellin, peptidoglycan, which are present on the surface of different bacterial pathogens. They also recognise the genetic material of some viruses (dsRNA/ssRNA), and other ubiquitous components shared by other microorganisms (fungi, parasites) (Takeuchi and Akira, 2010). The ability to recognise different pathogens depend on which PRRs cells have, and therefore dictate the ensuing immune response. Pathogens will often activate multiple PRRs allowing cross talk between receptors and a more robust immune response.

The location of PRRs also varies within the cell, some are present on the cell surface (plasma membrane) and recognise extracellular pathogens. These are mainly present on immune and epithelial cells. Other PRRs are present within the cells and recognise intracellular pathogens, such as viruses (endosome membrane/cytoplasm). Intracellular PRRs can also be membrane bound and present within the endosome membrane or free within the cytoplasm. These are often found in all cell types (Chan and Gack, 2016). PRR cellular localisation is summarised in Fig. 1.

There are four main groups of PRR. Toll Like receptors (TLRs) are the most widely studied, C-type lectin receptors (CLRs), Retinoic acid inducible gene-I (RIG-I) like receptors (RLRs) and Nucleotide-binding oligomerisation domain-like receptors (NLRs). Cytosolic DNA sensors are another group of recently discovered PRRs (Chan and Gack, 2016). We will discuss the above in more detail below in relation to their role in recognition of viral pathogens.

Toll like receptors (TLRs)

In humans there are 10 functional TLRs (Medzhitov, 2001; Takeda and Akira, 2005). These are found as heterodimers or homodimers in the plasma membrane or endosome membrane (Lester and Li, 2014). TLR1, 2, 4, 5, 6, 10 are found in the plasma membrane, and TLR3, 7, 8, 9 in the endosome membrane (recognise intracellular pathogens). These signalling molecules consist of an extracellular domain that recognises PAMPs and an intracellular domain that has cell signalling capabilities, known as the Toll Interleukin Receptor (TIR) domain. TLRs present within the endosome have the signalling domain present within the cell cytoplasm and PAMP recognition domain present within the endosome. TLR3, 7 and 8 are the main TLRs that detect the presence of viral genetic material. TLR3 recognises dsRNA, and TLR7/8 ssRNA, which can either be the composition of the viral genome or it can be an intermediate produced during viral replication (Alexopoulou et al., 2001; Heil et al., 2004; Lund et al., 2004).

Fig. 1 Cellular localisation of Pattern recognition receptors (PRRs). Schematic shows the cellular localisation of PRRs. TLRs are located in the plasma membrane and endosome membrane. Those present in the plasma membrane detect extracellular pathogens and those within the endosome intracellular pathogens. The pathogen recognition domain is present outside of the cell (plasma membrane TLRs) or within the endosome, with the c-terminal signalling domain being present within the cytosol for both. CLR PRRs are also present within the plasma membrane and recognise extracellular pathogens. NLRs, RLRs and cGAS PRRs are all present within the cell cytosol and recognise intracellular pathogens.

As well as recognising viral genetic material, viral proteins have also been shown to activate a number of the cell surface exposed TLRs. Some examples include the cell surface exposed F protein of RSV, which can directly activate TLR4 (Funchal et al., 2015). This is also the case for the non structural protein (NSP) 1 of DENV, and surface glycoprotein of EBOV, which both also directly activate TLR4 (Modhiran et al., 2015; Okumura et al., 2010). Examples of TLR2 being directly activated by viral proteins include that of the measles hemagglutinin protein and the NSP4 of rotavirus (Bieback et al., 2002; Ge et al., 2013).

Once activated the TLRs undergo a conformational change which leads to recruitment of adaptor proteins to the signalling domain, this includes proteins such as Myeloid differentiation factor 88 (MYD88) (TRL7/8) or TIR-domain-containing adapter-inducing interferon- β (TRIF). This can also include Toll-interleukin-1 Receptor domain-containing adaptor protein (TIRAP) and TRIF-related adaptor molecules (TRAM)) (Takeuchi et al., 2000; Hayashi et al., 2001; Kawai et al., 1999). These activate a downstream signalling cascade which eventually leads to the translocation of transcription factors into the cell nucleus, which alters gene expression. This includes transcription factors nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B), Activator Protein 1s (AP1s) and Interferon Regulatory Factor (IRF) 3/IRF7, which are the end products of the NF- κ B, Mitogen activated protein (MAP) kinase and Interferon (IFN) signalling pathways respectively, resulting in expression of key genes of the innate immune system (discussed below). Signalling through TLRs is discussed in more detail in (Kawasaki and Kawai (2014); Takeda and Akira (2005))

C-type lectin receptors (CLRs)

The function of C-type lectin receptors in antiviral immunity and downstream signalling is nicely summarised in Bermejo-Jambrina et al. (2018) and Geijtenbeek and Gringhuis (2009). C-type lectin receptors are present within the plasma membrane of the host cell and recognise extracellular pathogens. They are predominantly on immune cells, such as dendritic cells (DCs) and macrophages. These PRRs recognise carbohydrate structures (recognised through their carbohydrate recognition domain), present on the pathogen surface glycoproteins such as mannose, glucan and fucose. Mannose being the one most predominantly recognised on viral pathogens. Some examples of these receptors which recognise viral pathogens includes DC-SIGN, which recognises mannose on Human immunodeficiency virus (HIV) and IAV (Gringhuis et al., 2007; Yu et al., 2017), DNCR-1 is able to recognise the vaccinia virus (Iborra et al., 2012) and CELC5A has been shown to recognise Japanese encephalitis virus (JEV) glycoproteins (Chen et al., 2012).

Downstream signalling after activation of the CLR is complex and the pathways activated varies depending on the CLR activated. Signalling through CLRs is summarised nicely in Geijtenbeek and Gringhuis (2009). Some CLR signalling pathways also cross talk with TLR signalling pathways further complicating the downstream signalling (Meyer-Wentrup et al., 2009). Activation of the IFN and NF- κ B signalling pathways, is similarly to TLRs, a key feature of activation of CLRs. However, as these receptors are predominantly on professional antigen presenting cells (APCs) the viral antigens are internalized and processed for presentation to T cells on major histocompatibility complex (MHC) molecules. Due to the antigen being from an extracellular source these are processed and expressed on MHC class II molecules and presented to CD4+ T helper cells (Engering et al., 2002; Gurer et al., 2008). DCs also possess a special ability to cross present exogenous antigen (extracellular) on MHC class I molecules (normally present intracellular antigens to T cells), allowing presentation of antigen to CD8+ cytotoxic T cells, which are key for the antiviral immune response (Schreibelt et al., 2012; Iborra et al., 2012; Zelenay et al., 2012).

Although activation of these PRRs is important in the induction of the antiviral immune response (Long et al., 2013; Chen et al., 2012). There are also multiple cases where viruses have adapted to avoid these receptors and can also use these receptors to aid infection and propagation, some examples include HIV, EBOV and Hepatitis C virus (HCV) (Hodges et al., 2007; Simmons et al., 2003; Ludwig et al., 2004).

Retinoic acid inducible gene-1 (RIG-1) like receptors (RLRs)

RIG-like-receptors are a trio of RNA helicases proteins with the RIG-I being the most recognisable member of the RLR family. Followed by melanoma differentiation antigen 5 (MDA5) and laboratory of genetics and physiology 2 (LGP2). All three have a key role in the cellular recognition of RNA viruses (Kell and Gale, 2015; Loo and Gale, 2011). During non-infectious periods, RLR proteins act as sentinels for viral PAMPs and are ubiquitously expressed at low levels in the cell. Both RIG-1 and MDA5 have a c-terminal caspase activation and recruitment domains (CARDs) which directly interacts with other downstream signalling molecules activating an immune response (Loo and Gale, 2011). Upon viral RNA recognition, these proteins change their structural conformation activating a downstream signalling cascade, eventually forming a complex with the mitochondrial antiviral signalling (MAVS) adaptor protein. Resulting in preferential expression of the type III IFNs and other interferon stimulated genes (ISGs) (Dixit et al., 2010; Chan and Gack, 2016).

These receptors have been shown to be key in recognising infection by a number of important viruses such as IAV, HCV, Hepatitis B virus (HBV), West Nile virus (WNV), picornaviruses etc. However, these viruses have evolved mechanisms to avoid detection via RLRs and some of these are summarised in Chan and Gack (2016).

Nucleotide-binding oligomerization domain-like receptors (NLRs)

Nucleotide-binding and oligomerisation domain NOD-like receptors (NLRs) are PRRs expressed in the cytosol. NLRs constantly assess the cytosolic environment for signs of infection, molecules that can affect the cellular equilibrium (such as toxins), or even imbalances in metabolic processes. There are 22 NLRs with nucleotide-binding oligomerization domain-containing protein (NOD) 1/NOD-2 and NOD-, LRR- and pyrin domain-containing 3 (NLRP3) being the most well characterised. These receptors detect

different stimulus including viral RNA and DNA. NLRs contain multiple domains, core NLR domains such as NLRC1 and NLRC2, have a pivotal role in the activation of the mitogen-activated protein kinase (MAPK) producing Type I IFNs (Anand et al., 2011). Whereas some receptors activate the inflammasome and caspase pathways. Activation of inflammasome is achieved through NLRP1, NLRP3, and NLRC4 (Malireddi et al., 2010; Masters et al., 2012; Thomas et al., 2009), resulting in the breakdown of pro-interleukin-1 β (pro-IL-1 β) and pro-IL-18. This caspase-1-modulated breakdown initiates the mechanisms for pyroptosis, which is cellular death due to pro-IL-1 β and pro-IL-18 (Malireddi et al., 2010).

RNA viruses can activate the NLRP3 inflammasome, as demonstrated in a study where murine macrophages exhibited caspase-1 activation due to influenza virus and rotavirus (Kanneganti et al., 2006). IL-1 β secretion was NLRP3-dependent in an *in vitro* model where encephalomyocarditis virus (ECMV) and vesicular stomatitis virus (VSV), challenged DCs and macrophages (Rajan et al., 2011). The NLRP3 inflammasome in THP-1 cells can be activated by measles virus, leading to the expression of IL-1 β (Komune et al., 2011) where in other instances the NLRP3 inflammasome can be activated by human RV and viroporin 2B protein (a pore-forming protein of HRV) (Triantafilou et al., 2013). This is achieved through the increase of Ca²⁺ concentration in the cytosol (Shrivastava et al., 2013).

Similarly to the above PRRs these viruses have evolved mechanisms to avoid detection via NLRs and some of these mechanisms are summarised in Chan and Gack (2016).

Cytosolic DNA sensors

Recognition of viral DNA is also important to identify infection by viruses with DNA genomes or RNA viruses that use DNA intermediates during viral replication (such as HIV). This is recognised by cytosolic DNA sensors such as cyclic GMP-AMP synthase (cGAS) which works in unison with the adaptor protein STING (Ishii et al., 2006; Ishikawa and Barber, 2008), and interferon- γ (IFN γ)-inducible protein 16 (IFI16) (Goubau et al., 2013). These are ubiquitously expressed in almost all cells. These sensors do not distinguish between host and pathogen derived DNA (White et al., 2014; Barber, 2015). However host DNA is localised in the cell nucleus so responses to self-DNA are avoided. Upon activation a downstream signalling cascade ensues resulting in activation of the IFN and NF- κ B signalling pathways, similar to other PRRs (Ishikawa et al., 2009). A detailed understanding the role of these PRRs in viral infection is reviewed in Abe et al. (2019) and Chan and Gack (2016).

Downstream signalling after PRR activation

Three main pathways are activated by PRRs, is summarised in Fig. 2. Focus in this chapter will be on the Interferon (IFN) pathway due to its critical importance in the immune response to, and clearance of viral infections.

Fig. 2 Signalling through pattern recognition receptors (PRRs). Schematic shows signalling through PRRs, using TLRs as an example. Upon activation adaptor proteins bind to the c-terminal (TIR) signalling domain of the TLR. For TLRs this is TIRAP/TRIF/MyD88/TRIF. This activates a signalling cascade which activates further proteins in the cascade, eventually resulting in activation of transcription factors NF- κ B, AP1s and IRF3/7. These transcription factors are subsequently translocated into the cell nucleus where they bind to the promoter regions of target genes, turning on transcription of these genes. This includes cytokines, chemokines and Interferons. All PRRs function similarly however the adaptor proteins and signalling cascade proteins differ. The pathways activated may also differ with some PRRs preferentially activating certain pathways.

Interferon (IFN) pathway

Interferons (IFNs) are key members of the cytokine family that are vital components of the anti-viral innate immune response (Levy et al., 2011; Schulz and Mossman, 2016; Hoffmann et al., 2015). There are three types of IFN, type I, II and III. Type I IFNs, are made up of 17 cytokines, type II a single cytokine, and type III IFNs 4 cytokines. Type I (especially IFN- α and IFN- β) and Type III IFNs (IFN- λ) are the key families of cytokines that play essential roles in the anti-viral immune response. These families of cytokines are mainly produced in response to activation of PRRs that detect viral nucleic acids (such as TLR3, RIG-1, MDA5, TLR7). Activation and production of IFNs are able to restrict viral replication and spread through modulating cell survival, replication and protein translation, they also promote tissue repair, and induction of adaptive immunity. Eventually facilitating viral clearance.

Due to their wide ranging effects on the host their expression is tightly controlled. Partly due to the fact these small proteins can effect multiple host cells. Type I IFNs signal through IFNAR1 (interferon alpha and beta receptor subunit 1) and IFNAR2, which is present on most nucleated cells (Gibbert et al., 2013). Whereas Type III IFN signal through a IL-10R2 (most cells)/IFNLR1 (epithelial cells) heterodimeric receptor, whose effects are more restricted to epithelial cells (Sommereyns et al., 2008).

Once expressed and secreted IFNs bind to IFN receptors on the host cell surface, these activate a downstream signalling cascade, through phosphorylation of Janus tyrosine kinase (JAK) proteins, the JAK1 and tyrosine kinase 2 (TYK2) (Schneider et al., 2014). This promotes recruitment of other signalling proteins, signal transducer and activator of transcription proteins (STAT1 and STAT2), which again are activated through phosphorylation. This is referred to as the JAK/STAT pathway. These STAT proteins then combine with Interferon regulatory protein (IRF) 9 to form a heterotrimeric transcription factor complex called IFN-stimulated gene factor (ISGF) 3. This complex translocates into the host cell nucleus, where it binds to the interferon stimulated response elements (ISREs) promoter, inducing the expression of numerous interferon stimulated genes (ISGs) (Schneider et al., 2014).

These genes have far reaching effects on the host and target all aspects of the viral life cycle (reviewed in Schoggins, 2019; and Yang and Li, 2020). Some examples include the family of Tripartite Motif Family (TRIM) proteins which have been shown to inhibit translation of numerous viral pathogens, this includes TRIM22 which has been shown to prevent transcription factor binding to the HIV-1 promoter region (Hattmann et al., 2012). This protein is also upregulated during viral infection with HBV/HCV, Epstein Barr virus (EBV) and Rubella virus infection, suggesting it may also play a role here in viral infection control (Su et al., 2002; Wieland et al., 2004; Mo et al., 2007). TRIM32 ubiquitinates the IAV PB1 polymerase marking it for degradation (Fu et al., 2015). These are just a few examples and more are discussed in detail in reviews by Schoggins (2019) and Yang and Li (2020). However, because of their importance in the antiviral immune response, viruses have adapted ways to avoid this response, which is discussed later in this chapter.

NK- κ B pathway

NK- κ B pathways is one of the three main pathways activated in response to pathogen recognition. The family of five structurally related transcription factors (NF- κ B1, NF- κ B2, RelA, RelB and c-Rel) are involved in the activation/expression of cytokine and chemokine genes and genes involved in the inflammasome (Oeckinghaus and Ghosh, 2009). The activity of these transcription factors are regulated by being coupled to inhibitory proteins (Ik- β family) in the cell cytoplasm, and are therefore inactive. Activation of the NF- κ B pathway eventually results in the degradation of Ik- β and translocation of NF- κ B transcription factors into the nucleus, and ultimately induction of NF- κ B controlled genes. Signalling through the NF- κ B pathway and its role in the ensuing immune response is covered in detail in Liu et al. (2017).

Numerous PRRs activate this signalling pathway, which results in production of pro-inflammatory cytokines, chemokines and inflammatory mediators that have far reaching effects on different innate immune cells. For instance these cytokines impact T cell differentiation and activation (Oh and Ghosh, 2013) and recruit neutrophil to the site of infection (Liu et al., 2017).

Mitogen-activated protein kinase (MAPK) pathway

The final pathway activated by PRRs is the MAPK pathway. The MAPK pathway is comprised of highly conserved serine/threonine kinases that are activated in response to many stimuli, including viral components. Signalling through this pathway is propagated via phosphorylation of upstream MAP kinases. This pathway is responsible for regulating many cellular functions including cell differentiation, proliferation, and survival. The role of the MAPK pathway in viral recognition and removal is discussed in detail in DuShane and Maginnis (2019) and Kumar et al. (2018), but will not be discussed further here.

Innate immune cells in the antiviral response

Although the immune system is all interlinked and many cell types contribute to the antiviral immune response, we will specifically focus on a few key cells/mechanisms of viral removal. Other cells of the innate immune response, such as the professional phagocytes, macrophages and DCs, are also important in the antiviral immune response. Especially dendritic cells, which bridge the innate and adaptive arm of the immune response. However, these will not be discussed further, and their functions in regards to viral infections are reviewed in Gracia-Hernandez et al. (2020); Sang et al. (2015); Soto et al. (2020), and Marongiu et al. (2021).

Natural killer (NK) cells

Natural Killer (NK) cells have cytotoxic functions and can secrete cytokines when activated (Vivier et al., 2008). NK cells target host cells which are either infected, have genetic mutations, or have increased stress markers, removing cells that are no longer functional and restore homeostasis (Cichocki et al., 2014).

Once virally infected, host cells are a potential targets for NK cells, which recognise compromised cells by the activation of NK cell surface receptors. NK cells have two different types of cell surface receptor, activating and inhibitory receptors (Bartel et al., 2013; Biassoni and Malnati, 2018; Bryceson et al., 2006). Normal healthy host cells express MHC class I molecules on their surface, which are recognised by NK cell inhibitory receptors and promote self-tolerance (Paul and Lal, 2017; Abel et al., 2018). At the same time NK cell activating receptors bind to host cell surface motifs. Virus infected cells often (also tumor cells) lose surface MHC class I expression, preventing the NK cell inhibitory signal (renders them undetectable by CD8⁺ cytotoxic T cells), activating the NK cell.

NK cells once activated kill infected cells using similar mechanisms to cytotoxic CD8⁺ T cells, discussed in more detail below. Cell death occurs through release of cytotoxic granules (perforin/granzyme) onto infected cells, or via death receptor mediated apoptosis (Fas/FasL interaction). NK cells can also recognise and kill cells via antibody-dependent cellular cytotoxicity (ADCC) (Ochoa et al., 2017). Recognising antibody bound to the surface of infected cells. NK cells also produce a variety of cytokines, mainly IFN- γ and TNF. These potent inflammatory cytokines activate other immune cells at the site of infection (Nutt and Huntington, 2019).

Studies indicate the importance of these cells during viral infection as they actively remove viral infected cells. This has been shown for a number of viruses such as IAV, where NK numbers correlated to reduced disease severity (Björkström et al., 2021; Jegaskanda et al., 2013). However, these cells can also exacerbate chronic viral infections, through elimination and manipulation of viral infected immune cells, rendering the immune system less functional, allowing the virus to propagate further (Waggoner et al., 2011; Lang et al., 2012). Interestingly some viruses can also directly infect these cells rendering them non functional (van Erp et al., 2019).

Neutrophils and neutrophil extracellular traps (NETs)

Neutrophils are the most abundant circulating white blood cell in the body and are the first immune cells to move to the site of infection. Although predominantly associated with the anti-bacterial and anti-fungal immune response they have also been shown to play a role in the removal of viruses. The three main mechanism of pathogen removal are degranulation, phagocytosis and the most recently discovered mechanisms of Neutrophil Extracellular Trap (NET) formation. Their importance in viral infection is clear as in animal models where neutrophils numbers are depleted increased viral load and clinical symptoms are observed (Tate et al., 2011; Stacey et al., 2014; Haick et al., 2014).

Although phagocytosis is a key mechanisms for removal of bacterial pathogens by neutrophils, the role of this anti-microbial removal is controversial for viruses, as the presence of some viruses within neutrophils is not necessarily due to phagocytic uptake but could be due to viral infection of the neutrophil itself (Orenstein, 2000; Halfhide et al., 2011). In some instances active uptake of viruses has been confirmed and this has also been shown to be modulated through uptake of apoptotic viral infected cells, leading to virus removal (Grundy et al., 1998; Hashimoto et al., 2007).

NETs are the newest mechanism of neutrophil killing discovered in 2004 by Brinkmann and colleagues (Brinkmann et al., 2004). These are web like structures composed of the nuclear DNA of the neutrophil studded with the granular proteins, such as neutrophil elastase, myeloperoxidase and citrullinated histones. These have been shown to trap and kill pathogens including viruses, and also enable the neutrophil to increase its surface area to help prevent further spread of the pathogen. Again although mainly studied in the context of bacterial and fungal pathogens there are many examples where they have been shown to trap and neutralise viral pathogens, such as HIV, RSV and IAV (Saitoh et al., 2012; Cortjens et al., 2016; Hoeksema et al., 2015).

Viral induced NETs however have also been shown to cause damage to the host. This is the case for RSV Bronchiolitis in young infants. The virus itself seems to cause little damage to the host (Deng et al., 2018; Villenave et al., 2011; Herbert et al., 2020), but the level of neutrophils and neutrophil extracellular traps (NETs) found in the airways of young children during severe RSV bronchiolitis positively correlates to disease severity (Cortjens et al., 2016). This phenomenon has also been observed during IAV infection, RV infection in asthmatics and during SARS-CoV-2 infection (Cortjens et al., 2016; Zhu et al., 2018; Toussaint et al., 2017; Veras et al., 2020). These are just a few examples.

Adaptive immune cells in the antiviral response

B cells and antibody

The function of B cells, specifically those that produce antibodies (plasma B cells), have a well characterised role in the immune response to viruses (Radbruch et al., 2006). Production of antibody is the premise for all vaccines and these are effective against many viral pathogens (measles, rubella, smallpox, yellow fever, SARS-CoV-2, influenza etc) producing neutralising antibodies. In many cases these also produce long lived memory B cells, which recognise the same pathogen on future encounters, rapidly produce antibody (von Behring and Kitasato, (1890); Ahmed and Gray, 1996). Production of these two cell types in response to viral infection is summarised in Palm and Henry (2019) and Dörner and Radbruch (2007)). However, in some instances

production of antibody to viral infections are short lived such as that observed for SARS-CoV-2 and RSV, and this allows reinfection to occur (Antia et al., 2018; Lyski et al., 2021; Gaebler et al., 2021; Habibi et al., 2015; Siggins et al., 2021).

B cells also have antibody independent functions during viral infection. This includes primarily production of pro and anti-inflammatory (Bregs) cytokines which interact and modulate the immune response of other cells (Iwata et al., 2011; Shen and Fillatreau, 2015). They also present antigen to T cells on MHC class II molecules, which helps dictate the T cell response to viral antigens (Constant et al., 1995). Further information on these are summarised in Upasani et al. (2021) and Shen and Fillatreau (2015).

Cytotoxic T lymphocytes (CD8+)

Cytotoxic T cells (CTLs) are a key component of the adaptive immune system and are key for destruction of viral infected cells (Nutt and Huntington, 2019). These T cells recognise antigen, via their T cell receptor, presented in MHC class I molecules. MHC class I molecules are present on the surface of all nucleated cells within the body. Peptides generated within these cells, that are loaded onto MHC class I molecules, are from endogenous (intracellular) peptides. This includes peptides generated from host cell proteins, but also from intracellular pathogens such as viruses. There are multiple MHC class I molecules on a single cell, which can have give a readout of up to 10,000 proteins on the cell surface, this array is interpreted by CTLs and NK cells. Processing of peptides for the MHC class I pathway is nicely reviewed in Neeffes et al. (2011).

There are two main host cell killing mechanisms employed by CTLs to remove infected or tumour cells. Loss of function of these killing mechanisms by CTLs through genetic deficiencies such as, familial hemophagocytic lymphohistiocytosis (perforin dysfunction), shows increased susceptibility of these individuals to severe uncontrolled viral infections (Katano and Cohen, 2005).

One mechanism includes production and release of cytotoxic granules (similar to those produced by NK cells), which are mainly composed of perforin and granzyme (Voskoboinik et al., 2015). These are released from the CTLs in a directional manner towards the target cell to reduce bystander damage. This occurs as the T cell forms an immunological synapse between itself and the target cell, which is a highly organised structure made through the interaction with receptors and ligands on target cell and T cell surfaces. Perforin once released forms a pore in the host cell membrane, damaging it, but this also allows entry of the granzyme protein into the host cell. This protease once within the cell degrades cellular components such as protein or DNA, shutting down the production of viral proteins, and ultimately killing the infected host cell.

The second killing mechanism is through death receptor mediated apoptosis (Fas/FasL interaction) (Keckler, 2007). FasL expression is restricted to CTLs and NK cells, whereas Fas is expressed on the surface of many different cell types. The interaction of Fas, which has a death domain, with FasL on CTLs causes Fas to trimerise on the target cell surface, activating a downstream signalling cascade which ultimately leads to the activation of the apoptosis initiating caspase cascade, including caspase 8 and 10, which eventually results in the target cell undergoing apoptosis. This process is discussed in more detail in Yamada et al. (2017).

Finally CTL produce a number of pro-inflammatory cytokines such as TNF- α , IFN- γ and IL-2 which interact with other immune cells, promoting a T helper cell response and further CTL differentiation (Nutt and Huntington, 2019; Cox et al., 2013). One mechanism by which viruses are able to avoid these is through downregulating the expression of MHC class I molecules on the infected cells surface.

Cytotoxic T lymphocytes (CD4+)

CD4⁺ T cells are most commonly associated with T helper (Th) cell subsets, and recognise antigen presented in MHC class II molecules (on immune cells) with their TCR (Sant and McMichael, 2012). Naïve CD4⁺ T cells, when stimulated, can differentiate into a number of different effector T cell populations. The type of T cell produced depends on the specific cytokines within the microenvironment, which ultimately coordinates the type of immune response. The cytokines IL-12 and IL-4 respectively, induce differentiation into Th1 and Th2 subsets, and these were the first to be described (Mosmann et al., 1986). Further and more recent studies elucidated other Th subsets, such as Th17 cells, regulatory T cells (Treg), Th22, Th9 and follicular helper T cells (Tfh) (Raphael et al., 2015). These cells functions mainly through production of cytokines which interact with other cells of the immune systems and dictate the ensuing immune response.

More recently an unexpected CD4⁺ T cell subset was recognised, which have similar cytotoxic function as CD8⁺ CTLs. Their function and role in antiviral immunity is nicely summarised in Muraro et al. (2017). CD4⁺ CTLs, similar to CD8⁺ T cells, can release cytotoxic granules containing granzyme B and perforin (Fleischer, 1984), which when in direct contact with the target cell can kill them (Brown et al., 2016). They also kill target cells using the Fas/FasL interaction, as noted above. These mostly rare cells increase significantly in their numbers during transient and chronic viral infection, and have been shown to have cytolytic activity against viral infected cells (Nemes et al., 2010; Brown et al., 2016). This has been shown during Cytomegalovirus (CMV), Epstein-Barr virus (EBV), HCV, HBV and HIV infections (Facchinetti et al., 2005; Aslan et al., 2006; Appay et al., 2002; Rosenberg et al., 1997; Musey et al., 1997; van Leeuwen et al., 2004). Such is the importance of CD4 CTLs, they can replace CD8⁺ CTLs during chronic infections, as CD8⁺ CTLs lose their functionality. Further studies are being undertaken on this cell population to elucidate further their role in antiviral immunity.

Natural killer T cells (NKT)

Another cell type of potential importance during viral infections is the Natural Killer T cell (Gumperz et al., 2002; Gapin et al., 2001). These are innate like cells and can respond rapidly to antigen that has not been encountered previously. These cells contain an invariant TCR which recognise lipid antigens presented in a MHC class I like molecule (CD1d). They also have a number of cell surface molecules in common with NK cells, hence the name. Once activated these cells can produce a wide range of cytokines and chemokines which influence other cells of the immune system (similar to T helper cells) (Coquet et al., 2008; Paget et al., 2012), such as DC maturation (Fujii et al., 2003), B cell antibody production (King et al., 2011) and T cell polarisation (Godfrey and Kronenberg, 2004). These cells can also directly lyse infected cells using cytolytic proteins (granzyme/perforin), similarly to CTLs, however this is a CD1d-dependent mechanism (Kok et al., 2012).

Some evidence suggests these cells help protect against viral infection, but more research is still needed in this area. During influenza (H1N1) viral infection NKT cell numbers are reduced in patients with severe disease (Chen et al., 2010). However, when present these cells have been shown to selectively lyse influenza infected cells and reduce lung pathology (Kok et al., 2012; Paget et al., 2012). During chronic HBV infection, the frequency of circulating CD4⁺ NKT cells is lower in asymptomatic carriers (Jiang et al., 2011), but numbers increase after treatment (Tripathy et al., 2011). NKT cell numbers are also reduced during HIV-1 infection, due to viral infection of the CD4⁺ NKT cell subset, which occurs preferentially to conventional CD4⁺ T cells, due to the expression of multiple co-receptors (CD4/CCR5, CXCR4, and CXCR6) involved in viral fusion and cell entry (Motsinger et al., 2002; Fernandez et al., 2014; van der Vliet et al., 2002; Sandberg et al., 2002; Fleuridor et al., 2003). NKT cell numbers recover following effective antiretroviral therapy (van der Vliet et al., 2006). More information on NKT cells and their role during viral infection is summarised in Slauenwhite and Johnston (2015) and Tupin et al. (2007).

Viral avoidance of the immune response

Despite the arsenal of antiviral mechanisms in place to prevent viral infection and recognise and destroy viral infected cells, viruses have evolved ways to avoid detection by the immune system in a number of different ways. Some of these will be discussed in more detail below.

Interference of viral antigen presentation on MHC class I molecules

As discussed above CTLs can recognise and kill viral infected cells through recognition of viral peptides in MHC class I molecules (on all nucleated cells). A commonly used viral strategy to evade CTL killing mechanisms is to interfere with the presentation of antigen in MHC class I molecules. This can occur through multiple mechanisms, but mainly via interfering with antigen processing in the infected cell, or by reducing the number of MHC molecules on the target cell surface. Examples of this are discussed in the following reviews Schuren et al. (2016),; Loch and Tampé (2005), ; Horst et al. (2011).

Ways in which viruses have been able to interfere with antigen processing within the target cell, which ultimately leads to reduced presentation of viral peptides to CTLs, includes: producing proteins that are resistant to antigen digestion by the proteasome. Proteins must first be digested within the target cell by proteases to allow short peptides to be loaded onto MHC class I molecules, preventing this degradation prevents these viral peptides being presented to CTLs. This mechanism is used by the EBNA-1 (Epstein Barr Nuclear Antigen 1) protein of EBV (Levitskaya et al., 1995). Some viruses also interfere with the Transporter associated with Antigen Processing (TAP) protein, which transports peptide antigens into the endoplasmic reticulum for loading into MHC class I molecules. This is the case for Herpes Simplex virus (HSV) where ICP47 (infected cell protein 47) interferes with the binding of the peptides to the TAP protein (Ackerman et al., 2006). This is also a mechanism used by CMV through protein US6 (Unique short 6 glycoprotein) (Lehner et al., 1997).

Other viruses reduce viral antigen presentation through interfering with MHC I presentation on the cell surface. This can target multiple steps in the production and trafficking of MHC in the cell (van de Weijer et al., 2015). Adenovirus is able to do this using its E3 protein, which forms a complex with MHC class I molecules to prevent antigens from being processed (Fu et al., 2011). CMV achieves this through multiple mechanisms, proteins US2 and US11 promote the rapid degradation of newly synthesised MHC class I complexes (Gabor et al., 2020). CMV gpm152 protein causes retention of the MHC class I molecules in the Golgi compartment through which MHC class I loaded with peptide are trafficked. Varicella zoster virus open reading frame 66 protein also performs this immune evasion tactic (Purohit et al., 2021). Further some viral protein of the Kaposi's Sarcoma virus (Kaposi's Sarcoma Virus ubiquitin ligase) promote rapid endocytosis of surface expressed MHC Class I and their subsequent degradation (Coscoy and Ganem, 2000).

Antigenic variation (antibody escape)

Antigenic variation is a key mechanism by which many different viral pathogens are able to avoid the adaptive arm of the immune system (antibody recognition). This is most notably utilised by the respiratory RNA genome viruses, such as Influenza viruses, coronaviruses and RVs (Duffy, 2018). One key feature that allows this to occur more readily in RNA genome viruses is the fact the RNA polymerase enzyme required for replication of the viral genome has no proof reading functionality (not the case for

coronaviruses) (Smith and Denison, 2012). Meaning during genome replication mutations are constantly being introduced into the genome. If these are beneficial genetic changes they will be selected for and that strain will thrive. These mutations can provide many benefits, such as increased ability to bind to the host receptor, increased replication capabilities, increased transmission capabilities, but also an ability to evade antibody binding if the mutation is present within a key cell surface epitope (Harvey et al., 2021).

Key examples of this have frequently been seen during the SARS-CoV-2 pandemic (Harvey et al., 2021). Many novel strains have emerged, which have been shown to have genome changes that give that strain a selective advantage. Changes specifically in the viral cell surface spike protein, which binds to the host receptor ACE2, are common (Forni et al., 2020). The B.1.1.529 variant (given the name Omicron), is a highly mutated variant with a significant number of gene alterations, including 26–32 mutations in the spike protein, some of which are associated with immune escape and higher transmissibility (Kannan et al., 2021; Zhang et al., 2021). This is also the protein target for all vaccines to date.

RVs also use this mechanism to avoid immune system detection. These are some of the most genetically diverse group of viruses (Stobart et al., 2017). They are categorised into three distinct serotypes, RVA, RVB and RVC. Within these serotypes there are over 150 different types, which are antigenically distinct from one another (Lau et al., 2007). It has been shown that antibodies produced against RV infection are robust and protective, however, antibodies produced against one type are not cross protective against another, allowing different strains to circulate annually (Lee et al., 2016). This has hindered vaccine design.

Influenza viruses also use this mechanism to avoid the immune system. This is known as antigenic drift, where genetic changes accumulate in the regions targeted by antibodies (Shao et al., 2017). For influenza viruses this is normally within the genes that encode the cell surface proteins haemagglutinin and neuraminidase, which bind to the host cell receptor (sialic acid) and cleave sialic acid to release the virus, respectively (Byrd-Leotis et al., 2017). Antigenic drift where we see minor genetic changes results in influenza strains that circulate annually causing epidemics. These strains can reinfect the host with antibodies being less effective, but in general a level of protection still exists, limiting the severity of infection (Shao et al., 2017; Wang et al., 2017).

Another phenomenon occurs in influenza viruses known as antigenic shift (Shao et al., 2017). This occurs in IAV only, which can infect humans and other animals, most notably pigs and poultry. This process which leads to the genetic rearrangement of two viral strains, is facilitated through the fact influenza viruses have a segmented RNA genome (Krammer et al., 2018). This allows easier reassortment of the genes during infection (two distinct viruses infect the same cells), which produces novel strains from reassortment of the zoonotic strains that can jump species barrier into humans, or from reassortment of a human and zoonotic strain (Sun et al., 2020). These strains have never before been encountered by humans, therefore there is no immunity (antibody) to prevent infection and disease can often be very severe. This phenomenon generates pandemic influenza strains, and since 1918 (Spanish flu) has generated 4 pandemics, with varying severity (Saunders-Hastings and Krawski, 2016).

Although not technically avoidance of the immune system, RSV for reasons unknown does not produce long lasting immunity. This means that antibodies produced against one strain one year are no longer present the following year, meaning that strain can reinfect the same person. This allows this virus to cause seasonal epidemics. This also seems to be the case in relation to antibodies produced against SARS-CoV-2, with evidence showing antibodies only last for roughly 6 months (Antia et al., 2018; Lyski et al., 2021; Gaebler et al., 2021; Habibi et al., 2015; Siggins et al., 2021).

Other mechanisms used by respiratory RNA viruses to avoid the immune system are nicely summarised in Kikkert (2020).

Modulation of PRR signalling

To avoid activation of the key signalling pathways many viruses have adapted to subvert the PRR signalling pathways, this is nicely reviewed in Bowie and Unterholzner (2008). This occurs either through preventing their activation or blocking the downstream signalling cascade. Vaccinia virus is able to subvert signalling via its protein A46R, which contains a TIR domain (Stack et al., 2005). This is able to sequester TIR domain binding adaptor proteins, preventing activation of the downstream signalling pathways (Stack et al., 2005). TRIF, a TLR signalling adaptor protein is cleaved by the NS3–4A viral protease of HCV. Cleavage of TRIF results in its inactivation rendering it unable to activate the downstream signalling pathways during HCV infection (Li et al., 2005). Viruses such as EBOV and IAV can also sequester their genetic material from the environment to prevent activation of the TLRs (Cárdenas et al., 2006; Hatada and Fukuda, 1992).

Avoidance of the RLR PRR is also a common adaptation of viruses. They modify the structure of their genetic material to avoid detection by these important PRRs. This can involve adding a cap structure to viral RNA making it mimic host mRNA. The ability to do this can be using viral encode capping enzymes or can involve stealing host encoded cap proteins, known as cap snatching (e.g. IAV) (Plotch et al., 1981). Alternatively viruses can protect their genetic material via adding a protein to protect it (e.g. VPg protein of picornaviruses) (Flanagan et al., 1977). Genetic material can also be sequestered to prevent detection by PRRs. Many viruses encode RNA binding proteins, that shield the dsRNA species from recognition by PRRs. Examples include Vaccinia virus E3L protein, EBOV viral protein (VP) 35 (Haasnoot et al., 2007) and HIV Tat protein (Weeks et al., 1990). Other viruses produce proteins that directly interact with signalling molecules involved in the RLR pathways, such as the V proteins of many paramyxoviruses (Andrejeva et al., 2004) and NS1 protein of IAV (Mibayashi et al., 2007).

Viral avoidance of cytoplasmic DNA sensors using similar strategies is summarised in review Abe et al. (2019).

Modulation of the IFN response

IFN, especially type I and type III IFN are key players in the antiviral immune response, as discussed above. Therefore many viruses have evolved ways in which to avoid this key immune response. Some key examples of this will be discussed below.

EBOV has multiple mechanisms that allow it to avoid the host IFN response. Two key viral proteins involved in this include the VP24 and VP35, which inhibits the activation of the IFN-stimulated genes through preventing STAT1 translocation into the host nucleus, and inhibits IFN production through preventing phosphorylation of IRF-3, respectively (Messaoudi et al., 2015; Fanunza et al., 2019). *In vitro* and *in vivo* (murine infection model) studies, where mutations have been introduced into these proteins, show reduced viral replication, increased host IFN response and severe attenuation compared to infection with strains containing the wild type proteins (Hartman et al., 2008a,b, 2006; Lubaki et al., 2016).

Deficiencies in the IFN response to SARS-CoV-2 infection have also been identified as a hallmark of disease, aiding viral replication and disease pathology. It is suggested to use multiple mechanisms to prevent the IFN response, including: inhibiting IFN induction by evading host PRR sensing or disrupting IFN signalling cascades, interfering with host protein production which included IFNs, and suppressing IFN action (reviewed in (Min et al., 2021)). Some examples of how this is achieved is via methylating the 5'-end of viral mRNA by NSP16/NSP10, which then mimics host mRNA (Viswanathan et al., 2020). This makes the viral genome undetectable by host PRRs. Multiple other viral proteins have the ability to interfere with the IFN signalling cascade, including SARS-CoV-2 PLpro (papain like protease) which can directly cleave IRF3, NSP6 inhibits IRF3 activation, NSP1 can suppress STAT1 transcription factor phosphorylation and its nuclear translocation, all which suppress IFN production (Xia et al., 2020; Moustaqil et al., 2020).

Some viruses also inhibit the initial binding of IFNs to their cognate receptors (IFNAR) on host cells. This includes IAV haemagglutinin protein, which tags the IFNAR1 protein for degradation (Xia et al., 2015). The NS5 protein of WNV can inhibit IFNAR1 intracellular trafficking and glycosylation and therefore surface expression of this receptor (Lubick et al., 2015).

Hiding within immune cells

Some viruses are also able to modulate the immune system through the infection of, destruction of and modulation of immune cells function. The most notable example of this is HIV, which infects CD4+ T cells, NKT cells, macrophages and DCs (Kruize and Kootstra, 2019; Harman et al., 2011). This phenomenon may be due to the virus having a broad cell tropism, as the host receptor is expressed on many different cell types, or this may be a more immune cell targeted infection. In some instances it can also be hard to prove whether the virus is able to actively infect and replicate within immune cells, or whether this is an artefact of viral phagocytosis by antigen presenting cells.

EBOV has a broad cell tropism and can infect many different cell types, this however includes some antigen presenting cells such as macrophages and dendritic cells, for which EBOV seems to have a preference for. This is also the case for other filoviruses and is reviewed in Olejnik et al. (2011). Evidence suggests that active replication of EBOV occurs within these cells (Geisbert et al., 2003; Ryabchikova et al., 1999; Johnson et al., 1995). Both of which play a key role in the ensuing immune response, especially dendritic cells, which bridge the adaptive and innate immune response. Although work is still ongoing as to the effect of infection of immune cells in EBOV infection, current studies suggest this induces a pro-inflammatory state (Bray and Geisbert, 2005). This over exuberant immune response and apoptosis of lymphocytes is associated with poor disease outcomes (Baize et al., 1999).

RSV has been found inside neutrophils (Halfhide et al., 2011). These are important cells in RSV disease as their number in the lungs, as mentioned above, directly correlate with disease severity (McNamara et al., 2003). The presence of RSV within neutrophils is controversial and it is still unclear if this is due to infection of these immune cells or if this is due to phagocytosis of the virus (Halfhide et al., 2011). Whether this virus can infect and manipulate these cells for their own benefit is yet to be elucidated.

Viral latency

Another way viruses can avoid the immune system is to reside within the host in a latent form. This is a common feature of herpesviruses where after initial infection they become transcriptionally inactive. For herpes simplex virus the viral genetic material is retained within infected cells as circular episomes (not integrated into host DNA), however some herpesviruses can integrate their DNA into the host chromosome, such as EBV. Establishment of latency allows these viruses to infect their host for life. Viral latency is discussed further in Sorel and Dewals (2018); Brar et al. (2020) and Bennett et al. (2005), in regards to how these viruses avoid and manipulate the host immune response.

This chapter summarizes how viruses are detected during infection, the key cells involved in the antiviral immune response and ways in which viruses have evolved to avoid the host immune system. More in depth discussion on each topic can be found in the cited reviews.

Glossary

CR3 Complement receptor 3. Also known as Mac-1 (macrophage-1 antigen) or CD11b/CD18.

LC3 Microtubule-associated protein 1A/1B-light chain 3mAb—monoclonal antibody.

TRIF TIR-domain-containing adapter-inducing interferon β .

Abbreviations

APECED	Autoimmune polyendocrinopathy candidiasis ectodermal dystrophy
BCL10	B-cell lymphoma/leukemia 10 protein
BTk	Bruton's tyrosine kinase
CARD9	Caspase recruitment domain-containing protein 9
Fas/FasL	Fas/Fas ligand
ITAM	Immuno-receptor tyrosine activation motif
KIR	Killer Ig-like receptor
MALT1	Mucosa-associated lymphoid tissue lymphoma translocation protein 1
MyD88	Myeloid differentiation primary response 88
NADPH	Nicotinamide adenine dinucleotide phosphate
PAD4	Protein arginine deiminase 4
PAR-2	Protease-activated receptor 2
PKC	Protein kinase C
PLC	Phospholipase C
SNP	Small nucleotide polymorphism
STAT1	Signal transducer and activator of transcription 1
STAT6	Signal transducer and activator of transcription 6
Syk	Spleen tyrosine kinase
α-GalCer	alpha-Galactosylceramide

Introduction

Human fungal pathogens are often ubiquitous in the environment or are members of the human commensal microbiota. Despite this high exposure rate, fungal infections are generally opportunistic and only cause disease in immunocompromised hosts. Fungal infections represent a wide range of human diseases from common superficial mucosal infections to life-threatening invasive infections (Brown et al., 2012). Mucosal/skin fungal infections are the most common human mycoses and include vulvovaginal candidiasis, oropharyngeal candidiasis and dermatophytosis (Fig. 1) (Brown et al., 2012; White et al., 2014). These fungal infections often associate with risk factors (such as antibiotic pre-treatment and poor hygiene) but can also affect apparently immunocompetent individuals. While they are not life-threatening, they are a significant healthcare burden and can severely affect quality of life and mental health, especially for those with recurrent infections. In contrast, invasive fungal infections mainly affect people who are immunocompromised as a result of iatrogenic factors, inherited immunological defects or acquired immunodeficiency (Table 1) (Brown et al., 2012).

The incidence of invasive fungal infections has been rising over the last few decades due to a growing at-risk population of immunosuppressed individuals. This is partly due to significant increases in the use of antibiotics, steroids and immune-modulating drugs in modern medicine (Clark and Drummond, 2019). Furthermore, there are now several documented congenital risk factors for severe fungal infections, including primary immunodeficiency disorders such as chronic granulomatous disease (CGD) and CARD9 deficiency. Global spread of viral infections which predispose to fungal infections (e.g. HIV) and the recent emergence of SARS-Cov-2 (COVID19) have also contributed to increased numbers of fungal infections and/or a worse

Fig. 1 Mucosal fungal diseases. Non-disseminated mucosal fungal infections are mostly non-life threatening, albeit they have a significant healthcare burden as they are often recurring or chronic in nature. Many are associated with a variety of risk factors and caused by a wide range of fungal species. Created with BioRender.com.

Table 1 Incidence and risk factors predisposing to invasive fungal infections in humans.

Fungal disease	Infectious agent	Disease burden	Fatality rate	Number of deaths	Tissues affected	Risk factors
Cryptococcosis	<i>Cryptococcus neoformans</i> , <i>Cryptococcus gattii</i>	~1.5 million	15–50%	~600,000	CNS, lung, kidney	Particularly prevalent in HIV/AIDS
Invasive aspergillosis	<i>Aspergillus</i> spp., mostly <i>A. fumigatus</i>	>1 million	30–70%	~500,000	Lung, CNS, kidney, heart, skin, eye, bone	Cancer, organ transplant, COPD
Invasive candidiasis	<i>Candida</i> spp.	>750,000	40%	~350,000	Lung, CNS, kidney, heart, skin, eye, bone, abdominal, liver, spleen	Cancer, organ transplant, surgery, hospitalization
Disseminated histoplasmosis	<i>Histoplasma capsulatum</i>	~100,000	15–30%	~80,000	Any, mostly liver, spleen or gastrointestinal	Particularly prevalent in HIV/AIDS
Pneumocystis pneumonia	<i>Pneumocystis jirovecii</i>	~500,000	15–50%	>250,000	Lung	HIV/AIDS, immunosuppressant drugs e.g. corticosteroids
Mucormycosis	Mucormycetes	~10,000	~50%	~5000	Multiple, mostly lung and skin	Diabetes, organ transplant, trauma e.g. burn

Data derived from (Bongomin et al., 2017).

clinical outcome (Lanternier et al., 2013; van Arkel et al., 2020). Mortality rates for invasive fungal infections have remained high in part due to inadequate diagnostics and treatments, and limited access to gold-standard antifungal drugs in low-middle income countries which carry the highest burden of infections (Benedict et al., 2017; Brown et al., 2012; Kozel and Wickes, 2014; Rodrigues and Albuquerque, 2018). Additionally, the efficacy of currently available anti-fungal drugs can be limited by the development of anti-fungal drug resistance. For example, *Candida auris* is a recently discovered multi-drug resistant species that causes significant mortality and morbidity, and has spread to at least 30 countries following its discovery in 2009 (Sabino et al., 2020).

Despite the impact of fungal diseases on human health, there remains much to be learned about the induction and regulation of anti-fungal immune responses. Yet, a greater understanding of antifungal immunity will be critical for the future development of diagnostics, vaccines and adjunctive immune-based treatments for fungal infection (Brown et al., 2012; Lionakis et al., 2017a). In this chapter, we summarize mechanisms of cellular antifungal immunity within the innate and adaptive immune systems, highlighting recent advances in our understanding and the areas requiring further research.

Innate anti-fungal immunity

Macrophages

Macrophages are myeloid cells of the innate immune system with a range of functions including tissue repair, removing dead cells, maintaining homeostatic organ function and uptake and clearance of invading microbes. During embryonic development, macrophages first arise from progenitors in the yolk sac, some of which seed developing organs to generate specialized tissue-resident macrophage populations (Fig. 2). Thereafter, hematopoietic stem cells (HSCs) in the foetal liver and the bone marrow give rise to monocytes which circulate in the blood and differentiate into macrophages upon entering tissue. The phenotype and function of monocyte-derived macrophages is shaped by environmental signals and the nature of the inflammatory insult (Epelman et al., 2014; Gordon and Plüddemann, 2017; Wynn et al., 2013). For example, high concentrations of IFN γ (as a result of bacterial or fungal infection) drives upregulation of the transcription factor STAT1 which supports polarization towards a pro-inflammatory and phagocytic phenotype, termed M1 or classical activation. M1 macrophages are particularly important for protective immunity against intracellular bacteria and fungi. On the other hand, exposure to IL-4 or IL-10 stimulated by extracellular pathogens such as dimorphic fungi, upregulates STAT6 resulting in an anti-inflammatory/tissue repair macrophage phenotype termed M2 or alternative activation (Italiani and Boraschi, 2014; Martinez and Gordon, 2014).

Macrophages are critical anti-fungal immune cells since individuals with genetic mutations that disrupt macrophage responses are highly susceptible to fungal infections. For example, patients with the dysfunctional *CX3CR1-M280* allele have a greater risk of developing disseminated candidiasis, which is related to the role of CX3CR1 in the recruitment and survival of monocyte-derived macrophages within the fungal-infected kidney (Lionakis et al., 2013; Salazar and Brown, 2018). Moreover, macrophage-depletion in mice results in higher fungal burden and decreased survival following infection with *C. albicans* (Lionakis et al., 2013; Salazar and Brown, 2018) and *C. neoformans* (Osterholzer et al., 2009; Sun et al., 2019). However, there are some contexts in which macrophages may promote fungal infection. For example, depletion of macrophages at a late stage of *C. neoformans* infection

Fig. 2 Heterogeneity of myeloid cells. Macrophages, monocytes and DCs exist as functional subsets driven by environmental cues and/or developmental pathways. The myeloid cell subsets discussed in this chapter are presented along with their defining markers and/or anatomical location. Created with BioRender.com.

reduced dissemination of the fungus to the spleen and brain in mice, indicating that some fungi may utilize macrophages for immune evasion and trafficking to distant organs (Charlier et al., 2009).

Macrophages detect fungal pathogens via pattern recognition receptors (PRRs) which detect PAMPs (pathogen-associated molecular patterns) within the fungus (see Box 1). Once activated by PRRs, macrophages initiate fungal uptake (phagocytosis) and killing and produce pro-inflammatory cytokines and chemokines. Macrophages phagocytose fungi using either opsonic receptors (e.g. CR3, Fc γ R) or non-opsonic receptors (e.g. Dectin-1) (Becker et al., 2015; Brown, 2011). Immune-modulating drugs that disrupt fungal phagocytosis by macrophages have demonstrated the importance of macrophage-mediated phagocytosis for fungal clearance. For example, ibrutinib is a BTK inhibitor prescribed to patients with chronic lymphocytic leukemia and has been associated with the development of invasive fungal infections, particularly aspergillosis, which is thought to be related to the role of BTK in regulating Dectin-1-dependent phagocytosis of *A. fumigatus* (Bercusson et al., 2018; Fiorcari et al., 2020; Ghez et al., 2018; Lionakis et al., 2017b). Following uptake, fungi-containing phagosomes fuse with lysosomes to form an acidic phagolysosome compartment, which contains a milieu of anti-microbial enzymes and drives nutrient starvation within the fungus, facilitating fungal death. This is a highly dynamic process which helps accommodate the shape-shifting nature of some fungal species. For example, *C. albicans* can form long filaments called hyphae, and lysosome fusion with the phagosome enables extensive growth of the phagolysosomal compartment and is required for macrophage killing of this fungus (Westman et al., 2020). Fungal morphology and cell wall structure play a significant role in determining the outcome of phagocytosis. For example, *C. neoformans* fungi form giant Titan cells that are resistant to phagocytic uptake (Dambuza et al., 2018) and form an anti-phagocytic capsule that prevents immune recognition and phagosome acidification (De Leon-Rodriguez et al., 2018; Gilbert et al., 2015). Several fungal species produce melanin which has been shown to interrupt LC3-dependent phagocytosis, driven by Dectin-1 signaling (Akoumianaki et al., 2016; Andrianaki et al., 2018; Sprenkeler et al., 2016). These evasion mechanisms lead to persistence of fungal pathogens within macrophages, which has been implicated in enabling dissemination of some fungi, such as *C. neoformans* whose persistence within lung interstitial macrophages has been indicated to drive dissemination to the CNS (Santangelo et al., 2004).

Box 1 Innate recognition of fungi

Innate recognition of fungi by myeloid cells is mediated by several classes of PRRs including the C-type lectin receptors (CLRs), Toll-like receptors (TLRs) and NOD-like receptors (NLRs) which bind to components of the fungal cell wall and nucleic acids leading to the activation of intracellular signaling cascades and antifungal immune responses (Fig. 3) (Salazar and Brown, 2018).

Fig. 3 Innate recognition of fungi. Fungal PAMPs deriving from the fungal cell wall are bound by TLRs or CLRs expressed by myeloid cells. Recognition by these receptors activates intracellular signaling cascades mediated by MyD88 (TLRs) or SYK/CARD9 (CLRs), culminating in a cellular immune response (e.g. cytokine production). Created with BioRender.com.

CLRs: The CLRs are a large family of transmembrane receptors which share a carbohydrate recognition domain (CRD) that is either calcium-dependent (C-type lectin) or calcium-independent (C-type lectin-like) (Zelensky and Gready, 2005). Several CLRs have been shown to activate antifungal immunity in mice and humans, particularly the CARD9-coupled CLRs Dectin-1, Dectin-2, Dectin-3, and Mincle (Patin et al., 2019). Dectin-1 is the best-studied CLR in the context of antifungal immunity and recognizes β -glucan in the fungal cell wall. Upon β -glucan binding, the ITAM signaling motif within the cytoplasmic tail of Dectin-1 (or Fc γ R, the signaling partner of Dectin-2/3) becomes phosphorylated, resulting in the recruitment and activation of Syk kinase. This initiates a signaling cascade via the kinases PLC γ and PKC δ leading to the formation of the CBM signaling complex, composed of CARD9, BCL10 and MALT1. This activates phagocytosis and fungal killing pathways, and also drives production of pro-inflammatory cytokines through activation of transcription factors (e.g. NF κ B and AP-1) and the NLRP3 inflammasome (see below). Dectin-1 can also alternatively activate the Syk-independent Raf1 signaling pathway, driving IL-23 production to promote Th17 differentiation (Drummond et al., 2018; Lionakis et al., 2017a; Patin et al., 2019; Speakman et al., 2020).

Mice deficient in CARD9 or CARD9-coupled receptors have increased susceptibility to *A. fumigatus*, *C. albicans* and *C. neoformans* infection (Drummond et al., 2018). This is replicated in humans where deleterious mutations in *CARD9* result in a primary immunodeficiency disease that specifically predisposes to fungal pathogens, but not bacterial or viral infections. CARD9 deficiency presents with an organ-specific pattern of susceptibility with patients predominantly presenting with either subcutaneous skin infections, CNS candidiasis or extra-pulmonary aspergillosis (Lanternier et al., 2013, 2015; Rieber et al., 2016). Human deficiencies in single CLRs have also underscored the importance of this receptor family in antifungal immunity. Dectin-2 deficiency has been shown to promote susceptibility to pulmonary cryptococcosis (Hu et al., 2015), while Dectin-1 deficiency, caused by the Y238X polymorphism, was found to increase the risk of vaginal and oropharyngeal candidiasis, as well as invasive aspergillosis in stem cell transplant patients (Chai et al., 2011; Ferwerda et al., 2009).

TLRs: TLRs are a family of PRRs consisting of 12 members in mice and 10 in humans, which are expressed at the cell surface or on intracellular organelles. All TLRs have a PAMP-recognizing ectodomain, a transmembrane domain and a Toll/IL-1 receptor domain for signaling (Kawasaki and Kawai, 2014). TLRs bind a diverse array of fungal ligands including cell wall components (TLR2), mannans (TLR4) and fungal DNA (TLR9) (Patin et al., 2019). TLR signaling is reviewed extensively elsewhere (Kawasaki and Kawai, 2014); briefly, extracellular TLRs recruit the signaling adaptor MyD88 to activate AP-1 and NF κ B resulting in production of inflammatory cytokines, while intracellular TLRs signal through the adaptor TRIF to activate interferon responsive transcription factors, such as IRF3. MyD88-deficient mice have an increased susceptibility to multiple fungal infections, including *A. fumigatus*, *C. albicans*, *C. neoformans*, and *Histoplasma capsulatum*, while deficiencies in single TLRs

(Continued)

Box 1 (Continued)

promote susceptibility in a context-dependent manner (Salazar and Brown, 2018). However, MyD88 deficiency in humans does not appear to be associated with an increased susceptibility to fungal infections. Instead, MyD88-deficient patients die in early childhood from profound bacterial infections, presumably because CLR-CARD9 signaling is sufficient to protect against fungal infection in the absence of the TLRs (Von Bernuth et al., 2008).

NLRs: NLRs are an intracellular family of PRRs which can be divided into inflammasome forming (e.g. NLRP3 and NLRC4) and non-inflammasome forming (e.g. NOD1 and NOD2). Inflammasomes are large protein complexes that drive proteolytic cascades mediated by caspase enzymes culminating in the production of bioactive cytokines IL-1 β and IL-18. In mice, deficiencies in NLRP3 and NLRC4 promotes susceptibility to several fungal pathogens including *C. albicans*, *C. neoformans* and *A. fumigatus* (Patin et al., 2019). Until recently, the fungal ligands responsible for inflammasome activation were unknown, but exciting new studies have shed light on how these pathways become activated by *Candida* and *Aspergillus* fungi. *Candida* hyphae secrete a peptide toxin called Candidalysin which helps the fungus invade epithelial barriers and establish mucosal infections (Moyes et al., 2016). Candidalysin was recently found to activate the NLRP3 inflammasome in macrophages, promoting both fungal escape (by driving macrophage death) (Kasper et al., 2018) and the induction of IL-1 β -dependent protective immunity by microglia in the brain (Drummond et al., 2019). Fungal activation of inflammasomes can therefore have diverse consequences that are organ- and cell type-specific. Galactosaminogalactan, a component of the *Aspergillus* cell wall, was recently found to bind mammalian ribosomes and block translation, which acted as a trigger for NLRP3 inflammasome activation and induction of protective immunity (Briard et al., 2020). Thus, by studying fungal-mediated activation of these pathways, we have discovered novel mechanisms controlling inflammasome function.

To kill fungi, macrophages produce toxic compounds such as reactive oxygen species (ROS) which is generated by the enzyme NADPH oxidase. CGD patients have mutations in components of the NADPH oxidase complex (e.g. p47^{phox}) and are particularly susceptible to aspergillosis, although cases of candidiasis and mucormycosis have also been reported (Falcone and Holland, 2012). In addition to ROS, macrophages produce reactive nitrogen species (RNS) and nitric oxide (NO) following activation of the iNOS enzyme (Warris and Ballou, 2019). M1 macrophages express high levels of iNOS which enables the conversion of arginine to NO and citrulline. In contrast, M2 macrophages alternatively upregulate arginase to convert arginine to ornithine and urea, and so produce little NO (Rath et al., 2014). Nitrogen-dependent fungal killing by M1 macrophages has been shown to be protective in many fungal infections including cryptococcal meningitis. STAT1 knockout mice, which lack an M1 response, are highly susceptible to pulmonary *C. neoformans* infection resulting in increased lung/brain fungal burden and accelerated mortality (Hardison et al., 2012). STAT1 regulates expression of CXCL9 and CXCL10, which drive recruitment of CXCR3⁺ Th1 CD4⁺ T cells that promote fungal clearance by enhancing phagocytic and killing functions of macrophages (Hardison et al., 2012; Xu et al., 2020). The NO produced via iNOS can react with superoxide to generate RNS, which are important in host defence by inhibiting growth and killing of fungi, particularly *Candida* species (Ahmadi et al., 2016; Warris and Ballou, 2019). Mice deficient in iNOS show increased susceptibility to *C. albicans* infection, while application of NO has been shown to be beneficial in treating cutaneous fungal infections (Balish et al., 2005; Stasko et al., 2018; Warris and Ballou, 2019). As with phagocytosis, fungal pathogens may employ evasion strategies to circumvent macrophage RNS-dependent killing. For example, *C. albicans* inhibits NO secretion by down-regulating iNOS expression and activity while upregulating arginase, a process mediated by exposure to fungal cell wall chitin, which drives an M2-like phenotype in macrophages thereby aiding fungal survival (Wagener et al., 2017). Similar perturbations of iNOS/NO pathways have been observed with *Paracoccidioides brasiliensis*, *Blastomyces dermatitidis* (Rocco et al., 2011) and *C. neoformans* (Kawakami et al., 1997; Leopold Wager et al., 2016).

Tissue-resident macrophages often act as the front-line defence against invading fungi and promote rapid responses via chemokine production, which recruit and activate leukocytes. For example, microglia are CNS-resident macrophages that protect against *C. albicans* brain infection via the CARD9-dependent production of IL-1 β and CXCL1, which acts to recruit neutrophils that are required for fungal clearance (Drummond et al., 2015b, 2019). In the fungal-infected lung, alveolar macrophages are a major source of pro-inflammatory chemokine CXCL2 (Xu-Vanpala et al., 2020; Xu and Shinohara, 2017), which recruits neutrophils and monocytes. Interestingly, alveolar macrophages develop into heterogeneous populations during fungal infection, in which CXCL2⁺ populations drive inflammation and uptake more fungi, whereas CXCL2⁻ populations express C1q which limits excess neutrophil recruitment and pathological inflammation (Xu-Vanpala et al., 2020). Macrophage responses to fungi, particularly of tissue-resident macrophages, are therefore heterogeneous and dependent on fungal species/organ. As we learn more about the environmental cues shaping tissue-resident macrophage identity, it will be interesting to determine how fungal infection impacts on these pathways and how initial responses by tissue-resident macrophages contribute towards antifungal defence.

Monocytes

Monocytes are circulating myeloid cells that differentiate into macrophages or dendritic cells (DCs) following recruitment into tissues (Italiani and Boraschi, 2014). However, monocytes can also act as immune effector cells in their own right, mediating fungal uptake and producing inflammatory cytokines. Monocytes are classed into three subtypes: classic (inflammatory), intermediate, and non-classical (patrolling). These subsets are identified by expression of surface receptors, in which “classic” are identified as CD14^{high}CCR2⁺CD16^{int}CX3CR1⁺, “intermediate” as CD14^{high}CCR2⁺CD16^{int}CX3CR1⁺ and “non-classical” as CD14^{low}CCR2⁻CD16^{high}CX3CR1⁺ (Fig. 2). Equivalent subsets exist in mice which are defined by expression of Ly6C in addition to CCR2 and/or CX3CR1 (Fu and Drummond, 2020; Italiani and Boraschi, 2014). Classical monocytes account for the majority of circulating monocytes and are the main precursor for inflammatory macrophages/DCs. Patrolling and intermediate monocytes are

less well understood, however patrolling monocytes are believed to be involved in homeostatic functions and tissue repair, while intermediate monocytes have been observed to perform both classical and non-classical functions, dependent on context (Fu and Drummond, 2020; Italiani and Boraschi, 2014).

Monocytopenia, a condition defined by reduced numbers of circulating monocytes, promotes susceptibility to systemic fungal infections in humans including histoplasmosis, aspergillosis and cryptococcosis (Salazar and Brown, 2018; Vinh et al., 2010). Murine pulmonary *A. fumigatus* infection induces an influx of inflammatory monocytes into the lung, with similar observations seen in the kidneys of mice infected systemically with *C. albicans*. Monocyte depletion in these studies has shown that these cells are essential for clearance of fungal pathogens, either by acting as a source of macrophages and DCs which then uptake/kill fungi and activate adaptive immune responses (see “Dendritic cells” below), and/or by recruiting leukocytes via cytokine and chemokine production (Espinosa et al., 2014; Fu and Drummond, 2020; Hohl et al., 2009; Ngo et al., 2014). For example, monocyte-derived DCs produce CXCL9/10 in the fungal-infected lung to recruit plasmacytoid DCs (pDCs) which activate ROS production in neutrophils and promote fungal killing (Guo et al., 2020). Although monocytes exert many protective functions in the context of fungal infection, there is evidence to suggest that their role can also be detrimental to fungal clearance. For example, monocyte depletion during early *C. neoformans* infection was actually found to be protective by preventing an accumulation of M2 macrophages which support *C. neoformans* proliferation and survival (Fu and Drummond, 2020; Heung and Hohl, 2019). Furthermore, *C. neoformans* has also been shown to hijack monocytes and use them as “Trojan Horses” to invade the blood-brain-barrier (Santiago-Tirado et al., 2017).

In recent years, monocytes have been implicated in mediating innate immune memory, termed “trained immunity”, to fungal pathogens (Heung, 2020; Netea et al., 2016). Monocytes stimulated with either *C. albicans* or β -glucan undergo epigenetic and metabolic reprogramming, characterized by histone H3 acetylation and a switch from oxidative phosphorylation to glycolysis. These changes prime monocytes to respond faster and in a greater magnitude to a secondary fungal exposure (Heung, 2020; Netea et al., 2016). For example, mice infected with a non-lethal dose of *C. albicans* had a higher survival rate following challenge with a lethal infection dose, an effect that did not require lymphocytes (Quintin et al., 2012). This monocyte reprogramming requires Dectin-1 and Raf-1-signalling (Quintin et al., 2012) and appears to provide a broad spectrum of protection, since mice trained with the BCG vaccine are also more resistant to *C. albicans* infection (Netea et al., 2016). These studies have inspired interest in trained immunity as a therapeutic strategy, particularly for patients with defects in adaptive immunity and therefore unable to mount classical memory responses.

Dendritic cells

DCs are professional antigen-presenting cells that interact with T-cells and activate the adaptive immune response. DCs possess long dendrites decorated with PRRs which enable them to sample their surroundings and rapidly detect an inflammatory insult or infection, often resulting in the release of cytokines to activate other effector cells (Banchereau et al., 2000). DCs can be found circulating in the blood, but are also resident in lymphoid tissues and in various mucosal tissues such as the skin and gut (Eisenbarth, 2019). Once activated via PRRs, DCs migrate to lymph nodes where they present antigenic peptides to CD8 and CD4 T cells on MHC-I or MHC-II molecules, respectively (Banchereau et al., 2000). This process of antigen presentation leads to the development of an adaptive immune response (see “adaptive anti-fungal immunity”) which is critical for the clearance of some fungal pathogens, such as *C. neoformans* and endemic dimorphic fungi (e.g. *Blastomyces*, *Histoplasma*) (Verma et al., 2015). DCs are divided into different subsets based on developmental origin, location and immune function (Fig. 2) (Eisenbarth, 2019). HSCs in the bone marrow give rise to the common DC precursor, which can then go on to become conventional DCs (cDC, further subdivided into cDC1 and cDC2) or plasmacytoid DCs (pDC). Alternatively, monocytes can give rise to monocyte-derived DCs (moDCs), or embryonic precursors give rise to tissue-resident DC populations (e.g. Langerhans cells in the skin) (Eisenbarth, 2019; Satpathy et al., 2012).

During fungal infection, DC subsets exhibit context-specific functions that are necessary for fungal clearance. For example, pDCs play crucial protective roles in the *A. fumigatus*-infected lung by producing IFN α and TNF α in a TLR9-dependent manner, but have also been shown to dampen excessive inflammation in the fungal-infected vaginal mucosa (LeBlanc et al., 2006; Ramirez-Ortiz et al., 2011; Ramirez-Ortiz and Means, 2012). In the skin, DC subsets are classified by location and surface expression of Langerin, CD103 and CD11b into epidermal Langerhans cells and various dermal DC subtypes (Igyártó et al., 2011; Kaplan, 2010). These DC subsets exhibit distinct functions in the context of *C. albicans* skin infection, which depends on IL-17-dependent immunity and neutrophil recruitment for clearance. For example, Langerhans cells specifically promote the differentiation of IL-17-producing CD4 T-cells via IL-6 production, which requires recognition of *C. albicans* by Dectin-1 (Igyártó et al., 2011; Kashem et al., 2015a). In contrast, CD301b⁺ dermal DCs indirectly promote IL-17 mediated immunity following activation by the neuropeptide CGRP, released by nociceptive neurons in response to *C. albicans* skin invasion. Binding of CGRP by these dermal DCs drives their production of IL-23, resulting in the rapid activation of $\gamma\delta$ T cells to produce IL-17 (Cohen et al., 2019; Kashem et al., 2015b).

Neutrophils

Neutropenia and inherited defects in neutrophil function are strongly associated with an increased risk for candidiasis, aspergillosis and mucormycosis in humans (Desai and Lionakis, 2018; Hassan and Voigt, 2019). Neutrophils are short-lived phagocytes specialized for pathogen killing, particularly extracellular pathogens, that are rapidly recruited in large numbers to the site of

infection (Rosales, 2018). Neutrophils release granules that contain microbicidal enzymes such as elastase and myeloperoxidase, and also produce large amounts of ROS (Rosales, 2018). Furthermore, neutrophils can form neutrophil extracellular traps (NETs), a mesh of chromatin containing citrullinated histones and antimicrobial proteins (e.g. calprotectin) to trap and kill pathogens (Urban and Nett, 2019).

Mouse studies have shown robust recruitment of neutrophils into *Candida* and *Aspergillus*-infected tissues, driven by the upregulation of neutrophil-attracting chemokines and cytokines (e.g. IL-8, CXCL2) (Lionakis et al., 2011). This recruitment is a tightly controlled process involving a range of signaling pathways that are activated in a fungal species- and organ-specific manner. For example, we recently showed that *C. albicans* brain infection drives production of the neutrophil chemoattractants IL-1 β and CXCL1 from microglia in a CARD9-dependent manner, whereas production of other neutrophil chemoattractants (e.g. CCL3) were not required for neutrophil influx into the CNS (Drummond et al., 2019). In contrast, neutrophil recruitment to the *C. albicans*-infected kidney does not require CARD9 and is dependent on CCR1 signaling, which is upregulated by neutrophils at a late stage of infection (Drummond et al., 2015b; Lionakis et al., 2012). Although neutrophil recruitment is required to control fungal proliferation within the kidney, CCR1 knockout mice were found to have significantly reduced inflammation resulting in improved survival following *C. albicans* infection (Lionakis et al., 2012), highlighting the need to regulate neutrophil recruitment in order to strike a balance between fighting the infection and preventing immunopathology. In pulmonary *A. fumigatus* infection, neutrophil recruitment into the lung occurs in two distinct phases. First, epithelial cells in the lung produce CXCL2 via a IL-1 β -IL-1R/MyD88 signaling pathway, followed by CARD9-dependent signaling within monocytes/macrophages that controls the second wave of neutrophil recruitment and is required to activate fungal killing by neutrophils (Caffrey et al., 2015; Desai and Lionakis, 2018; Jhingran et al., 2015).

Neutrophil fungal killing is regulated by several signaling pathways. For example, neutrophil killing of unopsonized *C. albicans* requires CR3-mediated recognition and activation of a Syk/PI3K/CARD9 signaling pathway, while killing of opsonized *C. albicans* requires recognition by Fc receptors resulting in signaling through Syk/PKC and activation of NADPH oxidase (Gazendam et al., 2014). Another fungal killing mechanism employed by neutrophils is the activation of an apoptosis-like cell death pathway within fungal spores, which depends on neutrophil NADPH oxidase activation (Shlezinger et al., 2017). Lastly, the formation of NETs is thought to be particularly important for entrapment and killing of large fungal structures, such as hyphae formed by *Candida* and *Aspergillus* species (Urban and Nett, 2019), while NET components such as calprotectin have been shown to restrict nutrient availability to fungal cells (Urban et al., 2009). The generation of NETs requires NADPH oxidase (for ROS production) and the enzyme PAD4, which generates the citrullinated histones (Urban and Nett, 2019). However, the relative dependence on these pathways in different disease contexts, including fungal infection, is not yet well understood. Opsonized *C. albicans* yeasts and hyphae have been shown to drive ROS-dependent PAD4-independent NETosis, whereas un-opsonized *C. albicans* drives Dectin-2-dependent PAD4 signaling to generate NETs independently of NADPH oxidase (Guiducci et al., 2018; Wu et al., 2019). Formation of NETs against *A. fumigatus* also appears to be strictly dependent on NADPH oxidase/ROS, while the role of PAD4 is still unclear with some studies indicating PAD4-dependence for optimal NET-based fungal killing, and other studies finding no requirement for PAD4 (Clark et al., 2018; Röhm et al., 2014; Silva et al., 2020).

Platelets

Platelets are short-lived anucleate blood cells with established roles in hemostasis by preventing bleeding through thrombus formation (van der Meijden and Heemskerk, 2019). In recent years, platelets have been appreciated to also help regulate immune responses. Following vasculature damage and inflammation, platelets become activated and release an array of cytokines and chemokines through their α -granules, including platelet factor 4 (PF4), RANTES and IL-1 β , which recruit and activate leukocytes. Activated platelets also express specific surface receptors including P-selectin, CD40L and GPIb which enable their interaction with leukocytes (Assinger et al., 2019; Mezger et al., 2019).

Thrombocytopenia is a common complication of organ transplantation and hematological malignancies (both of which enhance the risk of invasive fungal infections), and has been independently associated with an increased risk of aspergillosis and candidiasis (Eberl et al., 2019; Tischler et al., 2020). In vitro studies have shown platelet release of activation factors (including CD40L and RANTES) in response to *A. fumigatus*, resulting in recruitment of innate immune cells and disruption of hyphal growth (Rambach et al., 2015; Rødland et al., 2010; Speth et al., 2014). In a mouse model of pulmonary *A. fumigatus* infection, platelet depletion significantly enhanced mortality, which was the result of significant bleeding caused by fungal invasion and reduced neutrophil-mediated fungal killing (Tischler et al., 2020). Thrombocidin-1, a component of human platelet α -granules, has a potent antifungal effect against *C. neoformans* which further supports the theory that platelets can have direct fungicidal functions (Krijgsveld et al., 2000). Indeed, high resolution microscopy has shown that platelets aggregate and directly bind to *A. fumigatus* and *C. albicans* (Perkhofer et al., 2008; Robert et al., 2000). Moreover, an in vitro study showed that *Mucor circinelloides* potently induced platelet aggregation and activation, mediated by recognition through GPIIb/IIIa and the platelet Fc receptor Fc γ RIIA (Ghuman et al., 2019). The receptors mediating direct interactions between fungi and platelets are still poorly understood, and it is not always clear whether the consequences of platelet activation are beneficial for host protection. For example, platelets can activate complement via P-selectin which enhances fungal clearance by driving opsonization and phagocytosis (Speth et al., 2004, 2014). However, excessive complement activation has been associated with pathologic thrombosis and infarction, serious complications that have been observed in patients with angioinvasive fungal infections such as mucormycosis and aspergillosis, particularly those with CNS involvement (Gundlach et al., 2019; Sherif and Segal, 2010).

In addition to direct fungicidal functions, platelets may mediate fungal killing indirectly via the recruitment of phagocytes. For example, neutrophils are strongly attracted to thrombi formed *in vitro* with *A. fumigatus* conidia and human whole blood (Fréalles et al., 2018). Platelet/macrophage interactions can also boost antimicrobial immunity. For example, CLEC-2/podoplanin interactions, which mediate platelet-macrophage binding, has been shown to be protective since CLEC-2^{-/-} mice have excessive inflammation and increased mortality following the induction of bacterial sepsis (Rayes et al., 2017). Indeed, GP1b/Mac-1 (CR3) interactions between platelets and macrophages can help drive an M1 phenotype which helps to promote bacterial clearance (Carestia et al., 2019). Further research is needed to establish whether similar interactions occur during fungal infection and what effect they exert on disease outcome.

NK cells, NK T cells and innate lymphoid cells

NK (natural killer) cells and innate lymphoid cells (ILCs) are lymphoid cells that do not have rearranged antigen receptors and respond rapidly to inflammatory stimuli in an innate-like fashion (Becker et al., 2015). NK T cells are a subtype of T cell which express the invariant T cell receptor (TCR) through which they recognize lipid antigens presented by CD1d (an MHC-like molecule) on antigen presenting cells (Tupin et al., 2007). ILCs are grouped by their functional/cytokine profiles into ILC1 (IFN γ /TNF α producing, includes NK cells), ILC2 (IL-4, IL-5, IL-13 producing) and ILC3 (IL-17, IL-22 producing) subpopulations. Most ILCs are found in high numbers at mucosal sites, allowing them to rapidly respond to invading microbes and barrier breaches (Eberl et al., 2015).

NK cells (ILC1) are cytotoxic cells involved in the direct killing of fungal pathogens, however they also secrete inflammatory mediators to activate and recruit other immune cells including macrophages. NK cells recognize fungal pathogens via their expression of TLRs, CLRs and NK activation/inhibitory receptors (Schmidt et al., 2017). The latter includes Ly49 and KIR receptors, which mediate either activation or inhibition signals in NK cells (Pegram et al., 2011). For example, NKp30 directly recognizes β -glucan on the surface of *C. albicans* and *C. neoformans* (Li et al., 2013), while NKp46 mediates recognition of adhesins in the cell wall of *Candida glabrata* (Vitenshtein et al., 2016). These recognition events lead to NK cell activation, resulting in the release of perforin-containing granules and fungal killing (Schmidt et al., 2017).

NK T cells produce significant amounts of IFN γ and are particularly important in *C. neoformans* infection where Th1 responses are protective (Kawakami et al., 2001). Indeed, a specific subset of NK T cells expressing TCR chain V α 14 was found to accumulate in the lungs of *C. neoformans*-infected mice in a CCL2-dependent manner, and depletion of these cells (e.g. using CCL2 KO mice) resulted in reduced Th1 immunity and increased fungal burden (Kawakami et al., 2001). Furthermore, non-specific activation of NK T cells using the lipid α -GalCer was shown to increase IFN γ production by NK T cells resulting in enhanced fungal clearance (Kawakami et al., 2001). However, NK T-cells can also promote pathologic inflammation and prevent induction of protective antifungal immunity. In mice infected with *C. albicans*, non-specific activation of NK T-cells led to reduced survival and increased tissue fungal burdens, which correlated with enhanced inflammation and neutropenia (Tarumoto et al., 2014). Indeed, animals deficient in NK T cells (*Ja18*^{-/-}) are more resistant to *C. albicans* infection (Haraguchi et al., 2016). Thus, the role of NK T-cells is clearly dependent on fungal species but whether organ-dependence also exists has yet to be determined.

The role of other ILC subtypes in fungal infection is still poorly understood and sometimes controversial. ILC2 are associated with a type 2 (Th2) response characterized by the production of IL-33 and IL-13, which worsen pulmonary *C. neoformans* disease severity and may be involved in driving allergic fungal disease (see “Fc ϵ R-expressing granulocytes”) (Castanhinha et al., 2015; Flaczyk et al., 2013; Müller et al., 2007). ILC3s produce IL-17, IL-22 and GM-CSF and are required for maintaining barrier integrity in the gut and oral mucosa (Mortha et al., 2014; Sonnenberg et al., 2012). In murine models of oral candidiasis, there is significant production of IL-17 which is critical for protection, since animals deficient in the production of this cytokine or its receptor are highly susceptible to uncontrolled infection. Both CD4 T-cells and ILC3s have been shown to produce IL-17 during oral *C. albicans* infection, however the relative contribution of these cell types and their importance remains controversial (Conti et al., 2014; Gaffen et al., 2011; Gladiator et al., 2013).

$\gamma\delta$ T cells

$\gamma\delta$ T cells are found in mucosal tissues such as the gut, and are characterized by their TCR which has γ and δ chain as opposed to the α and β chain found in conventional CD4 and CD8 T cell subsets, (Van De Veerdonk and Netea, 2010). $\gamma\delta$ T-cells rapidly produce large amounts of IL-17, similar to ILC3, and thus these cells have also been implicated in protective antifungal immunity within mucosal tissues (Drummond et al., 2015a). However, mucosal fungal infections that depend on Th1 immunity for protection may be limited by the action of IL-17A⁺ $\gamma\delta$ T cells, evidenced during *Cryptococcus neoformans* infection where these lymphocytes downregulate the Th1 response and are associated with poor outcome (Sato et al., 2020). Furthermore, depletion of $\gamma\delta$ T cells improved resistance to vaginal *C. albicans* infection, albeit a mechanism for this has not yet been established (Wormley et al., 2001). $\gamma\delta$ T cells may also enhance humoral immunity (mediated by B cells). For example, *in vitro* *P. brasiliensis* infection was shown to activate $\gamma\delta$ T cells which stimulated the production of antibodies, particularly IgM, by B cells (Munk et al., 1995). $\gamma\delta$ T cells therefore have diverse roles in antifungal immunity, although specific mechanisms underlying $\gamma\delta$ T-cell activation and influence on the infection outcome remain poorly defined.

FcεR-expressing granulocytes

FcεR-expressing granulocytes are particularly important in the development of hypersensitivity and allergic inflammation due to their function and location. These cells include basophils, eosinophils and mast cells, which are myeloid cells activated by IgE and Th2-associated cytokines, and share high expression of the IgE receptor (FcεR) (Stone et al., 2010). Due to the prevalence of fungal spores in the environment, fungi are a common cause of exacerbation of allergic inflammation. Fungi can therefore cause a severe form of asthma, termed severe asthma with fungal sensitization (SAFS), which is believed to affect at least 10 million people worldwide. Fungal allergy has been associated with several fungal species including *A. fumigatus*, *C. albicans* and *Alternaria alternata* (Agarwal, 2011; Denning et al., 2014; Simon-Nobbe et al., 2008).

Mast cells are found in mucosal tissues, releasing inflammatory mediators including cytokines, histamines and prostaglandins following activation and degranulation in response to various inflammatory stimuli including bacteria and fungi (Krystel-Whittemore et al., 2016). Mast cells express Dectin-1 and TLR2 which bind zymosan in the cell wall, leading to Syk signaling and the release of leukotrienes which promote vasoconstriction and mucus production (Olynych et al., 2006), as well as production of inflammatory mediators to recruit macrophages (Lopes et al., 2015) and activate IL-9-producing T-cells (Moretti et al., 2017). In vitro studies using mouse and human mast cells have shown *C. albicans* causes rapid degranulation and release of ROS to drive extracellular fungicidal activity, while other studies have shown that mast cells can phagocytose *C. albicans* yeasts resulting in intracellular NO production, but this does not appear to effectively induce fungal killing (Lopes et al., 2015; Nieto-Patlán et al., 2015; Pinke et al., 2016; Trevisan et al., 2014). Indeed, in vivo mast cells at the intestinal mucosa de-granulate and phagocytose *C. albicans* in the gut, but are unable to kill it, resulting in cell death and loss of barrier integrity (Renga et al., 2018).

Patients with fungal allergy and asthma commonly present with eosinophilia (Cockrill and Hales, 1999) indicating that these cells may regulate mechanisms of fungal allergic inflammation. Eosinophils release granules in response to *A. alternata* conidia and hyphae, both predominant fungal sensitizers in asthmatics. Eosinophils recognize *A. alternata* through β-glucan/CD11b binding or through eosinophil PAR-2 activation by fungal proteases, resulting in degranulation and cytokine release and ultimately facilitating fungal killing as eosinophil granules contain several cytotoxic molecules including MBP (major basic protein) and EDN (eosinophil-derived neurotoxin) (Matsuwaki et al., 2009). Basophils are also activated by IgE, as well as cytokines (e.g. IL-33) and TLR signaling, upon which they leave the blood and enter inflamed tissue where they release histamine and cytokines (Stone et al., 2010). Basophil recruitment has been implicated in the development of chronic allergy (Ghosh et al., 2013), but their function in fungal sensitization has not been extensively explored. Early studies indicated that basophil function in the context of *A. fumigatus* infection was regulated by surfactant proteins, which reduced basophil histamine release and inhibited IgE binding to *A. fumigatus*, helping to reduce pathologic inflammation that is typical of allergy and asthma (Madan et al., 1997).

Adaptive anti-fungal immunity

CD4 T cells

CD4 T cells recognize specific peptide antigen via their TCR in the context of MHC-II expressed on the surface of antigen-presenting cells (such as DCs, B-cells and macrophages). CD4 T-cells differentiate into several subtypes (including Th1, Th2, Th9, Th17 and Treg) in response to environmental signals and APC-derived instructions, which are classified based on expression of master transcription factors and cytokine profiles (Fig. 4) (Verma et al., 2015).

Th1 cells are defined by their production of TNFα and IFNγ, and are generally protective against invasive fungal infections. In humans, genetic mutations in *IL12R* and autoantibodies against IFNγ are both associated with increased susceptibility to candidiasis, cryptococcosis, coccidioidomycosis and histoplasmosis (Romani, 2011; Verma et al., 2015). Furthermore, adjunctive immune-based therapy with recombinant IFNγ has been shown to improve clinical outcome in patients with *Candida* and *Aspergillus*-induced sepsis (Delsing et al., 2014) and cryptococcal meningitis (Jarvis et al., 2012). Indeed, mice deficient in IFNγ or its receptor are highly susceptible to infections with *C. albicans* (Balish et al., 1998), *A. fumigatus* (Cenci et al., 1999) and *C. neoformans* (Chen et al., 2005). IFNγ secreted by Th1 cells drives macrophages towards an M1 phenotype, which is required for clearance of *C. neoformans* and *H. capsulatum*, as discussed above (Drummond et al., 2015a).

While Th1 cells appear to provide protection against disseminated fungal infections, Th17 cells are particularly important for activating mucosal antifungal defence. In the oral mucosa, Th17 cells drive the recruitment of neutrophils and activate production of antimicrobial peptides in response to *C. albicans* infection (Hernández-Santos and Gaffen, 2012). Human deficiencies in IL-17-mediated immunity (e.g. Hyper IgE syndrome or *IL17RA* mutations) increase susceptibility to chronic mucosal candidiasis (CMC) (Lionakis et al., 2017a; Romani, 2011; Verma et al., 2015), and this has been replicated in murine models of CMC where deficiencies in IL-17, IL-23 or CD4 T-cells leads to uncontrolled fungal proliferation at the oral mucosa (Gaffen et al., 2011; Hernández-Santos and Gaffen, 2012; Verma et al., 2015). The susceptibility of APECED patients to CMC was also thought to be due to dysregulated IL-17 immunity. APECED is an autoimmune disease in which a single infection, CMC, is a defining symptom (Ferre et al., 2016). Since many APECED patients were found to have autoantibodies against IL-17, this was thought to explain their susceptibility to oral *Candida* infections. However, a recent study has shown that APECED is associated with excessive IFNγ production at the oral mucosa by pathologic CD4 T-cells, damaging the epithelial barrier and presenting an opportunity for *Candida* invasion and infection (Break et al., 2021). Thus, the interplay between Th17 and Th1 at the oral mucosa must be exquisitely balanced to promote control of fungal proliferation (Th17) while suppressing barrier damage and initiation of infection (Th1). Why IFNγ overproduction at the oral mucosa solely promotes susceptibility to CMC in APECED patients, and not to other infections, is as yet unknown.

Fig. 4 CD4 T cell differentiation. Naive CD4 T cells differentiate into functional subsets following environmental cues from antigen-presenting cells. Each subset has unique context-specific functions regulated by the production of cytokines which is controlled by the expression of a master transcription factor. Created with BioRender.com.

Tregs are a subset of CD4 T cells that suppress inflammation in order to limit potential tissue damage (Vignali et al., 2008). For example, Tregs have been shown to downregulate Th2 responses in the lungs of *A. fumigatus* infected mice, reducing allergic inflammation within the airways (Montagnoli et al., 2006). Treg-mediated suppression can also promote specific types of immune responses by removing inhibitory signals. Th17 differentiation is antagonized by IL-2 signaling, and by acting as a sink for excess IL-2, Tregs can indirectly promote Th17 responses (Adler, 2007). This mechanism has been shown to be protective in oral *Candida* infection, where Treg-binding to IL-2 was shown to promote Th17 immunity and fungal clearance (Pandiyan et al., 2011).

CD8 T cells

CD8 T cells are cytotoxic T-cells activated by recognition of cognate antigen presented in the context of MHC-I, upon which they secrete pro-inflammatory cytokines and cytotoxic granules containing perforins and granzymes, resulting in killing of target cells and driving inflammation. CD8 T cells can also induce apoptosis of infected cells through Fas/FasL, and they are therefore important for killing viruses and cancers. CD8 T cell cytotoxicity occurs rapidly, but is controlled and limited by their antigen specificity (Zhang and Bevan, 2011).

CD8 T cells secrete several protective antifungal cytokines such as IFN γ and IL-17, and can also directly exert cytotoxic effects on fungal pathogens, including *C. albicans* and *H. capsulatum* (Kumaresan et al., 2018). In several fungal diseases, it has been shown that CD8 T cells may be able to compensate in the absence of CD4 T cells (e.g. in HIV-infected patients). For example, protection against *C. neoformans* pulmonary infection primarily relies upon Th1 CD4 T-cells. However, when CD4 T-cells are depleted in mice, the number IFN γ producing CD8 T cells was found to increase which helped to control fungal growth. Interestingly, the protective capacity of CD8 T-cells appears to be organ-specific as they could not compensate for the lack of CD4 T-cells within the brain, which was profoundly dependent on Th1 immunity for protection (Buchanan and Doyle, 2000; Huffnagle et al., 1994; Lindell et al., 2005). Since CD8 T-cells may be able to provide protection in a CD4 depleted environment, albeit in a context-dependent manner, there has been interest in stimulating CD8 T cell responses as a therapeutic strategy in patients at risk for fungal infections with compromised CD4 T cell function (Kumaresan et al., 2018). Indeed, mouse models have indicated that this strategy works in the context of blastomycosis and histoplasmosis, for which CD8 responses were found to be sufficient to provide vaccine immunity in CD4 T-cell-depleted mice (Wüthrich et al., 2003).

B cells

B cells provide humoral immunity and act as antigen-presenting cells. Once B cells exit the bone marrow, they can either circulate through the blood and secondary lymphoid tissues, searching for antigen, or become resident subsets such as spleen marginal zone (MZ) B cells (Hauser and Höpken, 2015). Antigen recognition occurs via the B cell receptor (BCR) and subsequently results in activation and differentiation into antibody-secreting plasma cells. Naïve B cells express IgM/IgD antibodies, and upon activation undergo T-cell-dependent somatic hyper-mutation and class-switching resulting in the production of high-affinity functional antibodies. Alternatively, activated B cells can develop into memory cells, a self-renewing population that remains in the body for many years and enables a rapid humoral response upon re-exposure to antigen (Cyster and Allen, 2019).

Patients with defects in humoral immunity, such as X-linked agammaglobulinemia or hypogammaglobulinemia (in which patients have a mutation in the BTK gene resulting in low numbers of mature B cells and therefore produce little or no antibodies), have increased susceptibility to some fungal infections including cryptococcosis and pneumocystis (Casadevall and Pirofski, 2012; Plebani and Lougharis, 2014; Verma et al., 2015). Similarly, patients prescribed therapies that deplete B cells (e.g. rituximab) have an increased risk of mucosal and disseminated candidiasis (Lin et al., 2007). Studies using B cell and/or IgM deficient mice have demonstrated a protective role for these cells in controlling *C. neoformans* infection, since animals lacking B-cells exhibited increased fungal burdens in the lung and brain and reduced survival rates (Rohatgi and Pirofski, 2012; Subramaniam et al., 2010; Szymczak et al., 2013). Antifungal antibodies, which most commonly target cell wall components such as β -glucan, promote protection against infection by enhancing macrophage phagocytosis and killing by binding Fc receptors expressed by myeloid cells (Casadevall and Pirofski, 2012; Lionakis et al., 2017a; Verma et al., 2015). This appears to be particularly important for *C. neoformans* infection, where antibodies are needed to overcome the resistance of these encapsulated yeast to phagocytosis, and likely explains the susceptibility of B-cell-deficient mice to this fungal infection (Rivera et al., 2005). Antibodies may also directly bind the fungal surface, disrupting growth and virulence (Brena et al., 2011; McClelland et al., 2010). Antibody binding to the fungal cell surface can further activate complement, and induce antibody-dependent cellular cytotoxicity mediated by NK cells (Nabavi and Murphy, 1986). In addition, antibodies can act intracellularly by driving maturation of fungi-containing phagosomes. For example, it was shown that opsonizing *H. capsulatum* with monoclonal antibodies increased phagosome acidification, thus reducing intracellular survival of the yeast (Shi et al., 2008). Within barrier tissues, antibodies (particularly IgA) are crucial for providing antifungal defence and limiting dissemination and invasive infection. For example, plasma cells residing in the meninges provide critical antifungal defence in the CNS, by secreting antifungal IgA which prevents *C. albicans* invasion of the brain, which is often lethal (Fitzpatrick et al., 2020). The GI tract is also protected by antifungal IgA; CD37-deficient mice, which overproduce IgA, were found to be significantly better protected from *C. albicans* gut infection, indicating that IgA provides critical control of commensal fungal populations and limits their dissemination (Van Sriel et al., 2009).

These protective mechanisms have resulted in optimism for vaccine development for fungal pathogens, as well as providing an opportunity to boost immunity in immunocompromised patients (specifically those lacking T cell responses) using immunoglobulin therapy. mAbs against *C. auris* have been shown to increase phagocytosis of the fungus by macrophages, and thus may be a therapeutic route for this inherently drug-resistant species (Rudkin et al., 2018). Furthermore, there have been a small number of clinical trials testing the efficacy of anti-fungal mAbs against *C. albicans*, *A. fumigatus* and *C. neoformans* that have yielded promising results, however none have yet resulted in a licensed therapy in humans (Di Mambro et al., 2019).

Conclusions

Recent years have seen numerous significant advances of our understanding of antifungal immune defence. Many of these advances have centered on analyzing organ-specific mechanisms of immunity. For example, the discovery of how meningeal B-cells and CARD9-expressing tissue-resident macrophages protect the CNS against *Candida* infection, and identification of heterogeneous alveolar macrophage populations promoting fungal clearance and limiting tissue pathology in the lung. These studies have highlighted how it is critical to focus on context-dependent functions of immune cells, which are shaped by their environment and interplay with local cells and molecules. Indeed, by specifically analyzing the cellular interactions occurring at the oral mucosa, recent work has uncovered the mechanism underlying the susceptibility of APECED patients to CMC, while studies analyzing platelet behavior in the peritoneum has revealed important interactions with macrophages that help control sepsis. These important new insights not only hold significant clinical potential in helping to treat invasive fungal diseases, but have also underscored how the study of antifungal immunity can enable a wider understanding of the functioning immune system.

Abbreviations

bp	Base pair
CCNV	Chromosomal copy number variation
CNV	Copy number variation
DNA	Deoxyribonucleic acid
eDNA	Environmental DNA
GATK	Genome Analysis Toolkit
Gb	Gigabase
GC	Guanine-cytosine content
GWAS	Genome wide association study
HPD	Highest posterior density
ICU	Intensive care unit
INDEL	Insertion/deletion
ITS	Internal transcribed spacer
MLST	Multi-locus sequence typing
mtDNA	Mitochondrial DNA
N50	50% of the assembly is in contigs of this length or larger
NCBI	National Center for Biotechnology Information
ONT	Oxford Nanopore Technologies™
OTU	Operational taxonomic unit
PCR	Polymerase chain reaction
PNW	Pacific Northwest
RFLP	Restriction fragment length polymorphism
RIP	Repeat Induced Point
RNA-seq	RNA sequencing
SNP	Single nucleotide polymorphism
SRA	Short Read Archive
TB	Tuberculosis
TE	Transposable element
TMRCa	Time to most recent common ancestor
WGS	Whole genome sequencing

Introduction

Fungi are a globally ubiquitous Kingdom, which diverged from the animal and plant Kingdoms approximately 1.5 million years ago (Wang et al., 1999). There are thought to be at least 140,000 fungal species that are heterogeneously defined based on morphological, physiological, mating and molecular features (Xu, 2020), making this Kingdom taxonomically diverse. Taxonomy has

separated this Kingdom based on morphological features into macroscopic fungi, such as those that produce fruiting bodies (i.e., mushrooms), and microscopic fungi, such as yeasts and molds. Yet the advancement of genomics has allowed other features, such as DNA sequences, to be incorporated to help define species (Taylor et al., 2000), and genotype information is now increasingly used in the identification of new and cryptic fungal species.

Current taxonomic classifications group fungi into eight phyla: zoosporic fungi (Cryptomycota, Chytridiomycota and Blastocladiomycota), Microsporidia, Zoopagomycota, Mucoromycota and Dikarya fungi (Ascomycota and Basidiomycota). There are increasing numbers of emerging fungal pathogens in all phyla, either due to altered pathogenicity or the availability of new biological niches, infecting animals, plants and humans (Fisher et al., 2016), providing public health and conservation threats, as well as threats to food security (Fisher et al., 2018). There have been a number of emerging pathogenic fungal species which have needed the application of high-throughput genomics in order to understand the mechanisms driving evolution of virulence, drug resistance and pathogenicity. For example, in the last decade, the newly described chytrid fungus *Batrachochytrium salamandrivorans* (Bs) has caused rapid declines in salamander populations in Europe (Martel et al., 2013, 2014); *Cryptococcus gattii* has expanded its range from endemic to non-endemic regions (specifically the Pacific Northwest (PNW)), causing fatal disease in humans (Fraser et al., 2005); and the emergence of *Candida auris*, a pathogenic yeast causing nosocomial disease (Sato et al., 2009). Research into these emerging fungal pathogens, among others, have highlighted elaborate species complexes, alongside highly recombinogenic and dynamic genomes (Farrer et al., 2013a; Fisher et al., 2013), which drive micro- and macro-evolutionary changes capable of ultimately overcoming host defenses, and survival in non-endemic regions. The complex life cycles of fungi means fungal genomes are capable of undergoing recombination due to sexual and parasexual reproduction, and clonal propagation due to asexual reproduction, leading to novel genetic diversity and evolving pathogenic lineages. It is clear that there is a need to understand the mechanisms of evolution, which can only be addressed using genomics.

Genomics in mycology came into its own after the completion of the yeast *Saccharomyces cerevisiae* draft genome in 1996 (Goffeau et al., 1996; Mewes et al., 1997). Since then, the number of complete genome sequences for fungi have increased exponentially, with re-sequencing projects producing hundreds of genome sequences for one fungal species. With this large amount of data, our understanding of genome evolution, ecological and geographical distributions (Vanhove et al., 2016), population structure (Rhodes et al., 2017b) and fungal reproduction (Farrer et al., 2011) have advanced. The fall in the cost of WGS (Balloux et al., 2018; Rhodes et al., 2014) has also enabled large projects dedicated to the evolutionary processes acting within populations and species that lead to adaptation and phenotypic differences (Liti et al., 2009; Peter et al., 2018; Rhodes et al., 2017a,b).

In addition to WGS, other “omics” approaches have been utilized, with great success, for various species of fungi to illuminate their biology. Transcriptomics, proteomics and metabolomics have impacted our current understanding of fungal biology, which when used in combination with WGS can comprehensively scrutinize an entire system. Whilst RNA-seq can confirm gene predictions and enhance gene annotations (Bruno et al., 2010; Zhao et al., 2013), it can also be a useful tool for identifying changes in gene expression and alternate gene splicing, which may have roles in drug resistance (for example, the increase in *erg11* expression in *Cryptococcus neoformans* (Sionov et al., 2010)) and virulence respectively (Grützmann et al., 2014). Some studies have used RNA-seq to identify changes in gene expression required for host survival, highlighting the complex nature of crosstalk between fungal pathogens and their hosts, especially when combined with host RNA-seq during infection (Chen et al., 2013; Muñoz et al., 2019).

Other advancements in ‘omics’ approaches can also infer methylation, a hallmark of epigenetic changes. Whole-genome bisulphite sequencing can profile cytosine methylation to 5-methylcytosine (5-meC) within cytosine-rich genomic CpG isolates. Whilst 5-meC seems to be absent in some fungi (e.g., *Saccharomyces* and *Pichia* (Capuano et al., 2014)), in *Neurospora* 5-meC within CpG islands are found within ex-transposons that are targets of RIP mutations (Selker et al., 2003). Hosseini et al. combined whole-genome bisulphite sequencing with RNA-seq for 10 *Neurospora* isolates to investigate genome-wide DNA methylation; they confirmed a conserved link between DNA methylation and RIP mutations, with TE content and DNA methylation patterns showing a phylogenetic signal also (Hosseini et al., 2020). It is likely that *Neurospora* genomes are influenced on an evolutionary level by the interplay between TEs and the host defense. It is perfectly feasible, therefore, that similar studies could be carried out in other fungi, such as *Cryptococcus* species, which are associated with TEs (Wang et al., 2010), to investigate the role of epigenetics in mechanisms of infection.

In recent years, rapid “real-time” sequencing has been used to sequence fungal isolates, particularly within an outbreak. The development of the Oxford Nanopore MinION (discussed further below) device allows sequencing to be completed in under 48 h within one’s own laboratory, instead of relying on a centralized sequencing center. MinION has been used successfully on fungal isolates (Dutreux et al., 2018; Rhodes et al., 2018), and it is feasible to assume that this could be used to provide rapid transcriptomic data also, akin to what has been observed in viral genomics (Kim et al., 2020; Moldován et al., 2018; Tombácz et al., 2018). The generation of long reads (as opposed to short reads up to 500 bp in length) of 1 kb or more using this rapid sequencing technology also has the potential to make the generation of draft reference genomes more common (Rhodes et al., 2018). This in turn would allow alignment-based analyses to be carried out. However, alignment-free approaches also have their place, which will be discussed below.

Whilst these approaches have mostly been applied to fungal pathogens of crops, humans and wildlife, there is also a need to apply to populations of fungi that are important for food production and ecosystem maintenance. The baker’s yeast *S. cerevisiae* has been used in fermentation throughout human history, creating domestication events, but is largely neglected by scientific research. Liti et al. applied genomics to produce WGS of more than 70 *S. cerevisiae* isolates, finding phenotypic variation and populations that were delineated along geographic boundaries (Liti et al., 2009), and found that human influence has led to cross-breeding and production of new variants. This study was followed up in 2018 with a large scale population genomics survey of over one thousand

S. cerevisiae genomes which supported an “out-of-China” origin for this fungal species (Peter et al., 2018). By using additional ‘omics approaches, such as transcriptomics and proteomics, there could be significant advancements on the understanding of significant gene regulation differences during alcohol fermentation, and potentially link these to specific phenotypic differences.

Using genomics to characterize variation in complex fungal genomes

Due to the complex nature of fungal genomes, variation can arise and manifest as single nucleotide polymorphisms (SNPs), INDELs, recombination, hybridisation, CNVs and CCNVs. There may also be larger, structural variation such as chromosomal rearrangements (such as inversions, translocations or deletions), which can be responsible for gains or losses of genes or entire segments of the genome. Finally, transposable elements can replicate through transposition, impacting the plasticity, architecture and evolution of fungal genomes (Lorrain et al., 2021).

These variations are detected post-sequencing during bioinformatic analyzes, where two or more isolates are aligned and compared for changes indicative of SNPs; these SNPs may cause an amino acid substitution (a non-synonymous mutation), or due to redundancy in the genetic code, the amino acid may remain the same. The advancement of next-generation sequencing has allowed the identification of CNVs and CCNVs (and partial CCNVs, such as a chromosome arm) by noting changes in the depth of sequencing relative to normalized coverage.

Hybridisation between organisms can generate progeny with novel genetic variations, and has been reported in most eukaryotes. It is hypothesized that as the genetic distance between parental isolates increases, heterosis (where progeny display traits that are superior to their parents) becomes more prevalent (East, 1936). Whilst heterosis is associated with phenotypic effects, it is possible to identify heterotic quantitative trait loci through genome-wide association studies (GWAS) using whole genome SNPs.

Whilst these sources of variation aid our understanding of the epidemiology of infection, virulence factors and potential drug resistance, they require careful detection due to the complex nature of fungal genomes. Fungal genomes are, on average, smaller than their animal and plant counterparts, yet they are generally larger than bacteria and viruses. The average genome sizes of Ascomycota and Basidiomycota fungi are 36.91 and 46.48 Mb respectively, and range from 8.97 to 177.57 Mb. Therefore, the computational processing power required is greater than that of viral and bacterial genomics, along with a need for more storage space for those data, which may be beyond the financial capacity of some laboratories. Prior to bioinformatic analysis, the quality of the sequence data needs to be high, with sufficient coverage to confidently call these variant. In order to do this, the DNA extraction method and library building protocols need to be carefully considered, before deciding on multiplexing and the sequencing machine used. For example, comparing Illumina TruSeq Nano DNA extraction kit provided better quality data and higher coverage at regions of low GC content when compared to the New England Biolabs NEBNext Ultra DNA extraction kit (Rhodes et al., 2014); it is therefore important to consider the percentage GC content of the genome prior to selecting a DNA library preparation kit.

Before undertaking sequencing, researchers must consider the quality of the reference genome (if there is one) and whether there is a thorough understanding of the organisms’ genetic makeup and relatedness to other known species. If one of these points are unknown, or even debateable, then de novo assembly, using long reads or implementing a hybrid assembly of long and short reads, would be required. Otherwise, alignments using short or read reads against a preselected reference genome can be completed. Alignments are generally quicker than assemblies, and the “best practices” for variant calling are more established from alignments than from assemblies. Generating alignments will be discussed in more detail below.

Assemblies

Giordano et al. presented a comprehensive comparison of two long read sequencers, PacBio and MinION, and the short-read Illumina MiSeq platform (Giordano et al., 2017). Long read sequencers are capable of producing reads of over 10,000 base pairs, with reports of maximum lengths of 100,000 bp, which can overcome complex genetic features such as repetitive regions (repeats) and copy number variations. As such, long reads are deemed as the “gold standard” for reference genome assembly. In comparison, the typical length sequenced for short reads is between 50 and 400 bp (Goodwin et al., 2016); as a result, attempts at assembling creates a fragmented genome, with contigs that are much smaller than the actual chromosome size. However, a drawback of long read sequencing is the higher rate of sequencing errors (5–20%) compared to the short read data (<1%) (Goodwin et al., 2016). These errors could negatively impact de novo assembly (where there is no a priori knowledge of the correct sequence order) for genome construction as the errors are not always randomly distributed. Therefore, it is common practice to combine short- and long-read sequences in a hybrid assembly, where scaffolding of high quality short-read assemblies is carried out by bridging the gaps using long-read data, and therefore resolving the high error rate and repetitive regions.

The cost of sequencing cannot be overlooked, as it is a major consumable, and sometimes financially unachievable, especially for laboratories in developing nations. Currently, the initial cost for the PacBio RS II platform is approximately US\$700,000, and costs US\$300 per Gigabase (Gb) of data generated. The recently released PacBio Sequel (costing US\$350,000 initially for the platform) has, however, decreased the cost per Gb sequenced to US\$13–26 (Fatima et al., 2020).

Oxford Nanopore Technologies™ (ONT) developed a disruptive sequencer, the handheld MinION, in 2014. ONT offer the MinION Mk1B platform for US\$1000, and charging approximately US\$300 per Gb (when purchasing flow cells in bundles). Coupled with the low computing requirements and short laboratory preparatory work, this was an attractive option for many genomics groups. More recently, ONT produced high-throughput platforms, such as the GridION (5 flow cells) and PromethION

		Initial platform cost	Cost per Gb
MinION		£240	US\$9
PromethION 48		£24,000	US\$0.16
MiSeq		US\$125,000	US\$350
Sequel		US\$350,000	US\$13-26
RS II		US\$700,000	US\$300

Fig. 1 Comparison of sequencing platforms, their initial setup cost and the cost per Gb sequenced. Third-generation sequencing platforms, namely those producing long read sequences, include the MinION and PromethION (both from Oxford Nanopore Technologies) and the Sequel and RS II from PacBio. Short read technology has been dominated by sequencing platforms such as MiSeq, developed by Illumina.

(24 or 48 flow cells), bringing the cost of sequencing in parallel with the PacBio Sequel platform (approximately US\$21–24 per Gb). ONT do however charge a software license and annual warranty for the PromethION of between US\$20–30,000, for PromethION 24 and 48 respectively. These sequencing platforms are compared in Fig. 1.

In their report, Giordano et al. found that both PacBio RS II and ONT MinION provided excellent continuity and completeness for nuclear chromosomes of *S. cerevisiae*, but not for the mitochondrial genomes (although the PacBio data did provide a more complete mitochondrial genome compared to MinION data (Giordano et al., 2017)). This presents a significant challenge, as mitochondrial genomes are essential for molecular dating as mtDNA provide uniparental inheritance. Mitochondrial genomes are used for phylogenetic and phylogeographic analyses of taxa as there is a lack of recombination, and is therefore more likely to approximate the history of divergence among species than other loci (Pozzi et al., 2014). In addition to lower depth with respect to the PacBio data, the MinION data also had a higher than average homopolymer content by at 30% (Giordano et al., 2017). In order to rectify this, improving in the polishing step of de novo assembly is required, which is both time consuming and computationally intensive.

These long-read only assemblies did improve when scaffolding the MiSeq data with the long reads (a hybrid assembly), but varied depending on the assembler used; whether scaffolding with ONT MinION reads or PacBio reads, the npScarf assembler (Cao et al., 2017) performed better than HybridSPAdes (Antipov et al., 2015) and SMIS (available from <https://github.com/fg6/smis.git>), assembling a more contiguous sequence, a better N50, and overall, requiring less computational power. Therefore, it is extremely important to consider the sequencing technology and software for handling sequence data from fungi when performing de novo assemblies.

Alignments

Sequence alignment arrange two or more sequences (whether nucleic or protein sequences) in order to identify regions of similarity and dissimilarity, which may indicate regions of evolution and functionality. Aligners that arrange two sequences (pairwise alignment) are usually based on the Smith-Waterman or Needleman-Wunsch algorithms. Both create a substitution matrix based on a scoring scheme, but the former is primarily concerned with local alignments, whilst the latter is concerned with global, complete sequences. The most commonly used aligner, BWA-mem (Li and Durbin, 2009), is based on the Needleman-Wunsch algorithm, and is recommended for high-quality queries, and is faster and more accurate than other versions of BWA. Bowtie2 (Langmead and Salzberg, 2012) is also memory and time efficient, and is also optimized for the alignment of RNA-seq data to a reference genome.

The importance of a high quality reference genome cannot be overstated. Reference genomes differ from draft reference sequences due to their completeness i.e., a low number of gaps in the sequence. It is also expected that a high-quality reference genome will have a low number of errors, and high percentage of sequence assembled into chromosomes (The Vertebrate Genome Project, 2018). Ideally reference genomes will also have gene annotation data also. If the reference genome is mis-assembled or there has been PCR error introduced into the reference genome, this will likely be reflected in the variant calling. If the assembly quality of the reference genome is poor, this could also lead to larger variation, such as structural variation, being mischaracterized or missed completely. Lastly, the alignment of short read sequences will also not be of high quality in the presence of high genetic variability, which may be experienced in genomes that have introgression events or high mutation rates. The Fungal Genome Initiative at Broad Institute, United States, has amassed a large collection of gold-standard, high-quality fungal reference genomes spanning a wide diversity of fungi. These reference genomes can be downloaded from the Broad Institute FTP site or NCBI, which is the primary repository for all genomic data. Links to examples of good quality reference genomes, the majority of which have gene annotation, can be found here: <https://www.broadinstitute.org/science/projects/fungal-genome-initiative/current-fgi-sequence-projects>.

Once sequence data has been aligned to a reference genome, variant calling can be performed in order to identify SNPs and INDELs. The GATK (McKenna et al., 2010) variant caller “HaplotypeCaller” can call SNPs and indels simultaneously via local de novo assembly of haplotypes in an active region. This allows for more accurate calling of variants, particularly in regions containing different types of variants close together. It is worth considering the ploidy of your organism of study, as some variant callers can only consider homozygous or heterozygous (biallelic) sequences, whereas some fungal species display trialleles and/or polyploidy (such as *B. dendrobatidis*, which display polyploidy (Farrer et al., 2013a)). Reads that contain multiallelic loci may not map to the reference genome correctly, resulting in the underrepresentation of diverging haplotypes (Pfeifer, 2017). GATK HaplotypeCaller currently requires ploidy to be defined as a parameter, as either haploid or diploid; therefore, alternatives for aneuploidy and polyploidy are required. The variant caller FreeBayes (Garrison and Marth, 2012) has become more popular as it calls variants based on Bayesian statistical frameworks and is capable of modeling multiallelic loci. The variant caller BISCAP (Farrer et al., 2013b) is computationally inexpensive and is able to call variants from polyploid organisms due to its use of the binomial probability distribution for expected error rates post-alignment. SNP calling has been extensively reviewed elsewhere (Altmann et al., 2012; Mielczarek and Szyda, 2016; Pfeifer, 2017), however there are some drawbacks, especially when applied to fungal genomes which are classed as “non-model organisms” (with the exception to *S. cerevisiae* and *Schizosaccharomyces pombe*). For example, some genes related to pathogenicity are located within repetitive regions. *Phytophthora infestans*, whilst strictly not a fungal pathogen but an oomycete, has been shown to possess a “two-speed genome,” with gene-dense and gene-sparse, yet repeat-rich, regions (Raffaele et al., 2010). In the case of *P. infestans*, it has been shown that gene-sparse regions (GSRs) contain effectors, such as a class of translocated proteins called RXLRs, and other pathogenicity factors (Haas et al., 2009) which have been shown to evolve rapidly and adapt to host defenses (Raffaele et al., 2010). Two-speed genomes, with GSRs rich in effector-like genes involved in pathogenicity, have also been identified in plant fungal pathogens such as *Fusarium* species (Laurent et al., 2016; Fokkens et al., 2018; Wang et al., 2017). In *F. graminearum* for instance, within these “fast subgenomes,” genes known to be involved in pathogen-host interactions (PHI) and pathogen-associated genes are all overrepresented (Wang et al., 2017). In some cases, such as the barley powdery mildew fungus *Blumeria graminis* f.sp. *hordei* (Frantzeskakis et al., 2018), and the wheat stripe rust fungus *Puccinia striiformis* f.sp. *tritici* (Schwessinger et al., 2018), secreted effector proteins are not predominantly found in GSRs; a one-speed genome has been proposed for these fungal pathogens (Frankzeskakis et al., 2019). Current research projects are focusing on assessing two-speed genomes in other fungal pathogens, including those affecting animals and humans.

Alignment-based approaches may not be able to characterize these repetitive regions, and indeed, most gold-standard variant calling pipelines for various fungal organisms exclude repetitive regions due to false positives (Chen et al., 2017; Lockhart et al., 2017; Rhodes et al., 2018). Therefore, some variants relating to pathogenicity are likely being missed in a multitude of genomics studies.

It is therefore extremely important to consider the tools and data currently available before undertaking a study involving short read sequencing. Whilst fungal genomes are relatively small, and can mostly be sequenced in the haploid phase, some fungi display aneu- or polyploidy, heterozygosity and phasing which can present issues in downstream analyses.

Taxonomy

Although nearly 150,000 species of fungi have been described, it is estimated that between 2.2 and 3.8 million are estimated to exist (Hawksworth and Lücking, 2019). Ascomycota and Basidiomycota, which together form the subkingdom Dikarya, diverged 1.2 billion years ago; this is in stark contrast to some diversifications within the plant kingdom, where mosses and vascular plants only diverged 680 million ago (Berbee and Taylor, 2010).

Previously, fungi were characterized based on macro- and/or micromorphological features (Singer, 1986). However, with advancements in technology and biomedical science, classification of fungal species has grown to include ecological factors, physiology, reproduction, and recently, DNA sequences. Whole genome level approaches are becoming increasingly employed as they overcome resolution issues faced in single- or multi-loci studies. Commonly used species concepts are summarized in Table 1.

The human fungal pathogens *C. neoformans* and *Cryptococcus gattii* have been the subject of much discussion over its species concept in the last decade. In their study, Hagen et al. using phylogenetic species concept and genetic diversity of 11 genetic loci in 115 isolates to recognize seven species: *C. neoformans* var. *grubii* (now referred to as *C. neoformans*) and *C. neoformans* var. *neoformans*

Table 1 Species concepts in fungi.

Species concept	Key criterion	Early proponent	Fungal examples
Biological	Interbreeding to produce viable and fertile offspring	Mayr 1942	Kerrigan et al. (1994)
Ecological	Shared ecological niche	Van Valen 1976	Trudell et al. (2017)
Evolutionary	Shared evolutionary history	Simpson 1951	Kwon-Chung et al. (2017)
Genotype	Distinct genotypes	Mallet 1995	Banke et al. (1997)
Morphological	Distinct features	Regan 1926	Linnaeus (1753) and Zang (1987)
Phenetic	High phenotypic quantitative similarity	Michener 1970	Singer (1986)
Phylogenetic	Monophyly	Rosen 1979	Hagen et al. (2015) and Wu et al. (2016)
Recognition	Shared mate recognition	Paterson 1985	Callac et al. (2003)

Adapted from Xu J (2020) Fungal species concepts in the genomics era. *Genome* 63: 459–468. <https://doi.org/10.1139/gen-2020-0022>.

(now referred to as *C. deneoformans*), and five species within *C. gattii* (Hagen et al., 2015). Kwon-Chung et al. proposed the new naming system was compatible with advances in phylogenetic theory, and recognized the complex biodiversity within the agents of cryptococcosis (Kwon-Chung et al., 2017). However, there were disadvantages to the proposal put forward by Hagen et al., including the low number of isolates tested (115), and the inclusion of only 11 genetic loci, which were used for an MLST-based phylogenetic analysis, representing 43% of the *Cryptococcus* chromosomes. Therefore, the full effect of genetic diversity and recombination on taxonomic classification of *Cryptococcus* species cannot be properly inferred. It has also been shown that *C. neoformans* and *C. gattii* are able to reproduce asexually, producing clonal isolates, therefore the biological species concept model may not be appropriate here. Given the production of lineage hybrid isolates, it was not clear whether reproductive barriers prevented gene flow between the newly proposed species. Indeed, genetic exchange is thought to occur between *C. gattii* lineages (now recognized as five separate species: VGI as *C. gattii*, VGII as *C. deuterogattii*, VGIII as *C. bacillisporus*, VGIV as *C. tetragattii* and VGIV/VGIIIc as *C. decagattii*), and is proposed to be responsible for the high genetic diversity, as well as the existence of clonal populations and populations resulting from sexual reproduction (Muñoz et al., 2018b).

Despite these concerns, Hagen, along with a substantial amount of researchers within the *Cryptococcus* community published their rebuttal in 2017 stating these species complex should be accepted (Hagen et al., 2017). As such, scientific literature generally accepts and uses the proposed nomenclature for *C. neoformans*, yet lineage names are still widely used for *C. gattii*. The proposed species nomenclature seems to have been premature here, especially with the discovery of a new lineage, VGV, where the typing method RFLP could not distinguish between this new lineage and VGIV (Farrer et al., 2019). Indeed, this lineage could only be distinguished using WGS, and subsequently, a novel RFLP method developed specifically for this lineage; it is therefore crucial to attain all the available genetic data via WGS before assigning novel species nomenclature, and document historical reproductive isolation through a genealogical concordance phylogenetic species recognition (GCPSR). This approach would identify shared genealogical partitions between lineages across multiple loci (up to whole genome level) as evidence of isolation, and thus, evidence of a species (Taylor et al., 2000). Given the availability of over 1000 whole genome sequences for *Cryptococcus* species, the resolution is accessible in order to document GCPSR within *C. neoformans* and *C. gattii*.

Xu (2020) proposed a Genome-sequence based classification and identification (GSCI) system, which would contribute to the stability of fungal taxonomy and accelerate the discovery of new fungi (Xu, 2020). Currently, nearly 6000 fungal genome sequences are available in NCBI, covering over 1000 fungal species; this wealth of data could provide enough resolution for investigations to establish species boundaries.

Sequence-based classification via barcoding

Many taxa cannot currently be classified by current species concept (Table 1) and nomenclature rules. It is hoped that with the increased availability of WGS that classification efforts will shift towards genome-based identification. However, DNA barcoding will likely remain important for some time.

Due to challenges in modern fungal taxonomy, there is an emphasis on genealogical approaches, including genealogical concordance (discussed briefly above) and phylogenomics. However, in many cases, DNA barcoding using the internal transcribed spacer (ITS) remains an option in metabarcoding studies for the identification of fungi. These metabarcoding studies trade accuracy and precision for speed, however they rely on the curation of databases in order to assign taxa. Therefore, definitive answers are not always possible as the reference database may be incomplete or improperly labeled (Nilsson et al., 2006). Some metabarcoding pipelines, such as QIIME (Caporaso et al., 2010), utilize reference OTU picking, which are highly sensitive to the level of curation in the reference database, although open reference OTU picking allows recognition of sequences that do not have a close match.

Environmental DNA (eDNA) metabarcoding is a novel method, and can rapidly document unknown fungal diversity, however the fungal community remains divided as to how best to name these species. Sequence-based nomenclature seems to be a viable approach. Environmental metabarcoding studies have provided 16 billion fungal ITS reads (Lücking et al., 2021), encompassing a huge amount of fungal diversity. Yet this diversity is not captured by culture-based sequencing, and a large amount of these data

may be incorrectly or incompletely named. There is also potential error here, hidden in the lowest common ancestor (LCA), which is included in pipelines such as QIIME and is commonly used in environmental metabarcoding. Therefore, metabarcoding data have to be interpreted with great care.

The use of genomics in the detection and management of fungal outbreaks

Genomics has proven to be a valuable tool for the analysis of viral and bacterial pathogen outbreaks (Faria et al., 2016; Quick et al., 2015, 2016); it was therefore a logical step to apply the use of genomics to outbreaks of fungal pathogens.

Recently, the human fungal pathogen *Candida auris* has emerged as a major global public health concern due to high drug resistance and high mortality rates, and high propensity for nosocomial transmission (Lockhart et al., 2017; Schelenz et al., 2016). Although first described in 2009, the first hospital outbreak was reported in 2016 in a central London specialist cardio-thoracic hospital (Schelenz et al., 2016); at the time it was the largest outbreak of *Corynebacterium auris* observed globally. Since then, *C. auris* has caused a “stealthy pandemic” (Rhodes and Fisher, 2019), emerging in all continents with the exception of Antarctica.

WGS has played a crucial role in shaping our understanding of *C. auris* and its life history. Considering prior to 2015 little was known about the genetics of this important fungal pathogen, as of early 2021 there are nearly one thousand deposited whole genomes within NCBI SRA. These genomic studies have allowed thorough investigation into the *C. auris* genome, showing it to possess over 5000 protein coding genes (Lockhart et al., 2017; Rhodes et al., 2018) and expresses several virulence factors (Larkin et al., 2017; Sherry et al., 2017), such as biofilm formation and adherence, similar to *C. albicans* (Borman et al., 2016; Larkin et al., 2017). These discoveries have been made possible by combining WGS and gene annotation pipelines, and later with RNA-seq guided gene predictions (Muñoz et al., 2018a).

Yet the largest role genomics have played in improving our understanding of *C. auris* has been in the investigation of outbreaks and transmission events. Whilst genomics are commonly used in viral and bacterial outbreaks (Ebola (Quick et al., 2016), Zika (Grubaugh et al., 2017), SARS-CoV-2 (Lu et al., 2020) and cholera (Weill et al., 2017, 2018), for example), genomics has not been regularly employed in outbreak investigation due to the complexity of fungal biology and large genomes. And whilst fungal infections are not new, they have only recently increased in prevalence (for both human and plant infections) over the last three decades (Fisher et al., 2013), as illustrated in Fig. 2.

Chow et al. estimated a Bayesian molecular clock phylogeny, dating the origin of each *C. auris* clade to within the last 360 years, and outbreak forming clades originating in the last 40 years (Chow et al., 2020). A recent study has suggested a marine origin for *C. auris* (Arora et al., 2021); it is therefore a logical step to include these marine isolates within the current global collection of WGS *C. auris* isolates to date the emergence of outbreak forming lineages and identify a likely geographic origin.

Genomic data can also be used to reconstruct infectious disease transmission; software such as *TransPhylo* (Didelot et al., 2017) can indicate who infected whom, including the potential existence of unsampled individuals who may act as missing transmission links. *TransPhylo* has been used successfully to create transmission networks for viral outbreaks of mumps (Stapleton et al., 2019) and bacterial outbreaks of TB (Hatherell et al., 2016), yet has not been applied to a fungal pathogen. Despite infection control measures being in place, an outbreak of *C. auris* in a neurology ICU was only reduced upon removal of temperature probes, thus preventing transmission (Eyre et al., 2018). It would be interesting to use WGS combined with transmission network software such as *TransPhylo*, to see whether the incidence of new cases could be reduced in a shorter timeframe.

Identification of mutation rates and molecular clocks

In order to understand molecular change(s) in terms of geological time, we need a molecular clock to infer the relationship between evolution and the genotypes and phenotypes observed. This is of particular interest for outbreaks of pathogenic bacterial and viral infections, and is becoming increasingly questioned in relation to outbreaks of pathogenic fungal infections to determine when the

Fig. 2 Recently, there has been an increase in prevalence of both plant- and animal-infecting fungi worldwide.

organism was introduced into the setting (whether this is the country or a specific place, e.g., a hospital) and emergence of drug resistance. In recent years, the dating of a molecular clock has been investigated in outbreaks of many fungal pathogens, including *B. dendrobatidis* (O'Hanlon et al., 2018), *C. gattii* (Roe et al., 2018) and *C. auris* (Chow et al., 2020; Rhodes et al., 2018). Heckman et al. were the first to apply multiloci data to date fungi, and assumed that sampling many genes would average out gene-specific selective pressures (Heckman et al., 2001). As a result, their study produced inconsistencies between fossil records and molecular data, which raised the question: which one is correct? If the molecular dates were incorrect, this would suggest a misunderstanding in molecular evolution (Berbee and Taylor, 2010).

One assumption that underpinned Heckman's study was that the molecular clock had the same rate for all eukaryotes. However, a few years later Peterson et al. showed that it was possible to assume multiple calibration points to show that molecular clocks do not have a uniform rate (Peterson et al., 2004). Within the same study, Peterson showed that by picking a slowly evolving clade for calibration, Heckman et al. estimated older ages than expected. Therefore, rate variation needs to be a feature when estimating molecular evolution in modern approaches to molecular clock rates. This can be achieved by allowing rates to vary across the different branches of a tree, which is implemented in Bayesian coalescent-based algorithms, such as BEAST (Drummond and Rambaut, 2007); this is referred to as a "relaxed molecular clock." As previously discussed with other computational tasks, dating the molecular clock in fungi is intensive.

The data type used for molecular clock analysis needs to be carefully considered also; some studies have used high quality non-recombining segments of the mitochondrial genome (O'Hanlon et al., 2018) (because, as discussed above, mitochondria provide uniparental inheritance, less recombination and can provide better estimates of divergence times), whilst others have used whole genome SNPs without regions of recombination removed (Chow et al., 2020; Roe et al., 2018).

C. gattii had predominantly been regarded as a tropical pathogen, causing a range of symptoms, including cryptococcal meningitis. The origin of *C. gattii* has been identified as being in South America, likely Brazil (Engelthaler et al., 2014; Hagen et al., 2013), whilst some studies place its origin in Australia (Billmyre et al., 2014). However, a lineage of *C. gattii*, VGII, first appeared in British Columbia in the PNW in 1999 (Byrnes et al., 2009; Kidd et al., 2007). Roe et al. used whole genome SNPs before assessing the temporal signal of the dataset, implementing root-to-tip regression analysis, whereby the tips were dated with isolate collection date (Roe et al., 2018). They then inferred evolutionary rates and the TMRCA in BEAST. The TMRCA for VGIIa, VGIIb and VGIIc were estimated at 87.99, 81.43 and 66.29 years prior to 2018. A logical progression of this study would be to estimate the divergence of VGII and other *C. gattii* lineages, and the date of *C. gattii* lineage arriving in the PNW.

Roe et al. tested the statistical fit of 10 different clock and demographic model combinations, which resulted in the relaxed lognormal clock being the best fit for VGIIa, and a strict clock being the best fit for lineages VGIIb and VGIIc. This benchmarking analysis highlights how the same molecular rate is not necessarily the same across eukaryotes; the VGII lineages are closely related, with chromosome structure highly conserved between the lineages (Farrer et al., 2015), yet the molecular rates are different. Despite this, the mutation rates for VGIIa and VGIIc, which used different molecular clocks, had similar rates: 1.59×10^{-8} SNPs per base per year (95% HPD, 5.54×10^{-9} to 2.93×10^{-8} and 5.54×10^{-9} to 2.04×10^{-8} respectively). VGIIb on the other hand, was calculated to have a mutation rate of almost double that of VGIIa and VGIIc, at 2.70×10^{-8} SNPs per base per year (95% HPD 6.75×10^{-9} to 5.23×10^{-8}). These rates were an order of magnitude higher than common neutral fungal mutations rates ($\sim 2.0 \times 10^{-9}$), which the authors suggested was due to microevolutionary rate because of successive clonal generations in the laboratory as opposed to a slower rate when using fossil records. The latter would likely be affected by purifying selection, whereas the PNW lineages are clonal in nature, leading potentially to higher mutation rates. Interestingly, whilst investigations into serially collected isolates of *C. neoformans* have also shown clonal relationships, some isolates display an inflated substitution rate due to nonsense mutations in DNA mismatch repair pathways leading to hypermutator evolution (Rhodes et al., 2017a).

The occurrence of hypermutator states has been confirmed in other studies on *Cryptococcus* species (Billmyre et al., 2017; Boyce et al., 2017), and also in *Candida* (Healey et al., 2016). Therefore there is a need to properly investigate and accurately estimate the substitution rates, which can be achieved by partitioning regions of recombination. This approach was used to date the origin of the *B. dendrobatidis* hypervirulent lineage BdGPL to the 20th century (Farrer et al., 2011). Another approach to molecular dating is to use mitochondrial DNA, which is non-recombining. This approach was used to date the emergence of *B. dendrobatidis* lineage BdASIA-1, which displayed hallmarks of an ancestral lineage, as the early 20th century, coinciding with the global expansion of commercial trade in amphibians (O'Hanlon et al., 2018).

Concluding remarks

Currently, whole genome sequencing techniques have surpassed typing methods to provide a wealth of data on fungal genomes for detection and characterization of genomic epidemiology, virulence traits and life histories. These data are an important weapon in the arsenal in the war against contemporary epidemics in plants, animals and humans (Fisher et al., 2018). Whilst there are still some challenges with these approaches, it is clear there are many advantages to using genomic techniques. It is therefore important to consider the tools being used in fungal species, and adopt "best practices." Whilst some of the gold-standard techniques require substantial financial and computational power, recent advancements (such as ONT sequencers) are making these approaches more available to those in developing countries; since the burden of fungal disease is highest in developing countries (particularly those that affect crops, which are mainly grown in developing countries (Fisher et al., 2013)), we in developed countries need to do more to ensure scientists in these countries are financially able to carry out research and avoid "helicopter science."

Finally, the rapid emergence of outbreaks caused by fungal pathogens requires collaboration between researchers on a global level in order to fully exploit and utilize the expertise available; it is clear that the current systems for the generation, storage and distribution of genomic data cannot be sustained unless collaborative efforts are initialized and maintained between global research groups. Together, these multi-factorial approaches will ultimately improve our understanding of fungal biology, and any threats posed to ecosystems, health, and biodiversity in an ever changing world.

Glossary

Antigen presentation Process by which antigens are taken up, processed, and presented to the immune system.

Autoimmunity Pathology arising as the consequence of self-reactive immune cells failing to distinguish self and non-self and attacking host cells and tissues.

Cytokines Signaling molecules that are produced by immune cells to regulate the immune response.

Immune evasion Diverse set of mechanisms that allow the parasite to escape the host immune response.

Immunopathology Pathology arising as a consequence of an over-reactive, unregulated, immune response.

Resistance Host defence strategy aiming at clearing the infection or at least controlling parasite population size.

T-cell subpopulations CD4⁺, CD8⁺, CD25⁺ Classes of lymphocytes expressing different surface molecules. CD4⁺ T cells are helper lymphocytes that contribute to polarize the immune response towards a Th1 or a Th2 response. CD8⁺ T cells are cytolytic cells that participate in cytotoxic reactions. CD25⁺ T cells are regulatory lymphocytes that contribute to the resolution of ongoing immune response by the production of anti-inflammatory cytokines (IL-10, TGF- β).

Th1 and Th2 CD4⁺ cells Division of the CD4⁺ T cells depending on the type of cytokines they produce. Th1 response is characterized by the production of Interferon- γ and Tumor Necrosis Factor- α and is usually triggered by infection with intracellular parasites; Th2 response is characterized by the production of Interleukin-4, IL-5, IL-6 and is usually triggered by infection with extracellular parasites.

Tolerance Host defence strategy aiming at limiting the cost induced by the infection.

Introduction

Parasites, both micro and macroparasites, represent a pervasive threat for their hosts. Microparasites usually refer to viruses and pathogenic bacteria, whereas the term macroparasite indicates parasitic protozoa and helminths. Macroparasites have higher genomic complexity and life cycles that require either vectors either one or several intermediate hosts to be completed (complex life cycles). To give a glance of the diversity of the possible life cycles adopted by parasites inducing human diseases, we might mention malaria parasites that are transmitted from vertebrate host to vertebrate host by competent mosquitoes, filarial nematodes relying on black flies, or schistosomes that have water snails as intermediate hosts (Fig. 1).

Upon entering the vertebrate host, parasites elicit a complex array of immune defenses that may or may not clear the infection. A relatively broad feature of parasitic infections is chronicity. In other words, contrary to many microparasite infections that can induce acute fatality, macroparasites usually tend to establish long-lasting, chronic infections. This pattern suggests that macroparasites can withstand the host immune response. Indeed, protozoa and helminths have evolved a diversity of mechanisms that subvert the host immune system to allow their persistence within the host.

Humans still pay a high burden to infectious diseases and parasitic infections. Although many parasitic diseases are nowadays mostly distributed in the rural areas of tropical countries, during the last decades, we have witnessed the emergence/re-emergence of a number of infectious diseases in the countries of the northern hemisphere. Broadly speaking mechanisms of parasite pathogenicity can be divided into two large classes: the direct effect of parasite growth and/or multiplication within the host; the indirect effect of an over-reacting immune response.

[☆]Change History: January 2021. G Sorci updated all sections except the introduction. The section on resistance/tolerance and Figure 1 have been updated.

Schistosomiasis

Schistosoma haematobium, *S. intercalatum*, *S. japonicum*, *S. mansoni*, *S. mekongi*

Fig. 1 Schistosome life cycle. Schistosome eggs are shed in the water with feces or urine. After hatching, miracidia infect different species of snails (the intermediate host), where they undergo successive generations of sporocysts. The infective stage (cercariae) is released into the water and infects humans through the skin. Within the human body, schistosomulae migrate through different organs. Adult male and female worms establish and reproduce in the mesenteric venules or the venous plexus of bladder, depending on the species. Parasite diversity and the diversity of immune effectors

As mentioned above, macroparasites regroup a large diversity of species with complex life cycles and a large spectrum of sites of infection in the final host. This diversity of parasite strategies elicits a variety of immune effectors in the final host; there is no universal response that provides protection to all macroparasites. This diversity of immune responses is illustrated by the following list of immune effectors and the corresponding parasite target: complement-fixing antibodies play a role against larval stages of cestodes, opsonizing antibodies can target extracellular protozoa, eosinophils play a role against schistosome eggs and larvae (Behnke, 1990; Kaufmann et al., 2002).

CD4⁺ T helper lymphocytes can differentiate into two distinct types that polarize the immune response into a cellular-type immune response (with the production of cytotoxic T-cells) and a humoral-type immune response (with production of antibodies). The two phenotypes (Th1 and Th2) are induced by a multitude of "environmental" factors, such as the activation of antigen presenting cells, the cytokine environment, or the nature and the dose of the stimulating antigen. Th1 and Th2 cells are characterized by a different profile of cytokine production. The production of interferon- γ mostly characterizes a Th1 polarized response, whereas interleukin-4 (IL-4), IL-5, or IL-13 are markers of a Th2 response.

Induction of Th1 versus Th2 response is associated with a variable pattern of protection/susceptibility to different parasites. For instance, infection with the protozoan *Leishmania major* in mice induces a Th1 response that confers protection, whereas Th2-prone individuals fail to control the infection. On the contrary, protection to nematodes and other helminth species is conferred by Th2-type response and Th1 contributes to establish a chronic infection. These observations subsequently led to the conclusion that

Th1 response should mostly be involved in the protection against intracellular parasites, whereas Th2 response should confer a protection towards extracellular parasites and pathogens.

The Th1/Th2 paradigm has been very useful to identify immune pathways that can lead to protection or susceptibility to specific parasites. However, the picture appears to be slightly more complex than this simple view, since other Th-cell phenotypes (Treg, Th17) and immune regulatory cytokines (IL-10, TGF- β) also intervene to establish the pattern of susceptibility/resistance to a given parasite.

As mentioned above, another source of complexity during a parasitic infection is that, contrary to viruses and bacteria, macroparasites express a diversity of antigens during their maturation within the final host. For instance, many nematode infections are acquired when the host ingests infective stages (eggs or L3 larvae). Upon ingestion, the larvae molt a few times until the adult stage is reached. Maturation can require the migration through different host tissues. For instance, *Ascaris* and *Strongyloides* parasites migrate into the lungs before establishing in the gut of infected humans. Other species, such as hookworms, that are acquired by a transdermal route (larvae penetrate through the skin) also migrate through different tissues before establishing in the gut. These infections clearly have the potential to elicit different immune responses in different tissues and to express a diversity of antigenic stimuli as long as they mature into the adult stage and they start to produce eggs.

Similarly, protozoa such as *Plasmodium* parasites have different stages that exploit different host tissues (liver, blood) and the immune response that is produced against one stage can be very ineffective against the other stage.

Innate immunity

Innate immunity to protozoa and helminths is the first line of defence that is activated within minutes/hours after the infection. Innate immunity is more and more recognized as playing a pivotal role in shaping the pattern of resistance/susceptibility. Innate effectors allow the immune system to keep parasite multiplication under control (for protozoa) or to kill infective stages of helminths until adaptive immunity takes effect.

As for the adaptive immune response, innate effectors can be divided into cellular and humoral mechanisms. Macrophages and granulocytes have the capacity to engulf and phagocytize invading organisms. The recognition by macrophages and granulocytes of non-self structures is based on receptors that bind to parasite antigens. For instance, the glycosylphosphatidylinositol (GPI) lipid anchor of many protozoa is recognized by protein kinases and induces macrophages to produce cytotoxic compounds and pro-inflammatory cytokines. Pro-inflammatory cytokines, such as TNF- α , IFN- γ and IL-12 stimulate another class of lymphocytes, the natural killer (NK) cells. NK cells further contribute to the production of pro-inflammatory signals such as IFN- γ and this early activation of NK has been shown to be important in the clearance of several intracellular protozoa (*Leishmania*, *Toxoplasma*, and *Plasmodium*).

Whereas macrophages, granulocytes and NK lymphocytes are cellular effectors mostly involved in the control of proliferating intracellular protozoa, mast cells and eosinophils have been suggested to be involved in the resistance to helminths. Eosinophilia is commonly observed in many helminthic infections. However, experimental evidence in support of the idea that eosinophilia is a defence against helminths is mixed and as it is usually the case, mast cells and eosinophils seem to play a role in conjunction with other effectors that facilitate their action, such as opsonic antibodies or NK cells. To date, the best evidence seems to indicate that eosinophils might play a role in the resistance to larval and egg stages of the trematode parasite *Schistosoma mansoni*.

Innate immunity can also involve humoral effectors. Complement activation is probably the most effective innate mechanism involving humoral effectors towards extracellular parasites. The complement system encompasses glycoproteins that are produced by monocytes and macrophages. Complement can be activated through two different pathways (antigen/antibody complex and mannose-binding lectin pathways). The cleavage of complement components (C) gives rise to elements that produce a cascade of events, such as the deposition of C3b on the surface of extracellular parasites, the production of C5a, a chemotaxis factor, or of C5b, initiating the membrane attack pathway.

More recently, group 2 innate lymphoid cells (ILC2) have been recognized to play a key role during the process of Th2-response against helminths in humans and animal models (Pelly et al., 2016). ILC2 produce key Th2-cytokines (IL-4, IL-5, and IL-13) and orchestrate immune (mast cell recruitment, alternative macrophage activation) and non-immune (mucus production, hypercontractility of smooth muscles) responses that help to expel helminths from the gut. Cross-talk between ILC2 and mast cells has also been shown, since Spi-B-deficient mice that have increased numbers of mast cells are more resistant (expel the parasite at a faster rate) to the infection with the gut nematode *Heligmosomoides polygurus*. This better resistance is due to the induction of IL-13 producing ILC2 (Shimokawa et al., 2017). In the same line, enhanced renewal of intestinal epithelial cells can also promote parasite expulsion in mouse models infected with the nematode *Trichuris muris*. Such "epithelial escalator" has been shown to be under control of IL-13 and the chemokine CXCL10 (Cliffe et al., 2005).

Adaptive immunity

As already mentioned, adaptive immunity relies on both cellular and humoral effectors. The universal feature of the triggering mechanism is the recognition of parasite epitopes by receptors that are expressed in different immune cells (T- and B-cells). Other cell types, such as the antigen presenting cells (APC), are devoted to the process and presentation of parasitic peptides to T- and B-cells through the action of transporter associated with antigen processing molecules (TAP) and MHC molecules that respectively transport and present parasite peptides to the cell surface where they can bind to T-cell receptors (TCR). Based on the type of CD4⁺

T cells that are activated during the infection, the acquired immune response will either involve the activation of another subfamily of lymphocytes (CD8⁺), with cytolytic properties, or the production of neutralizing antibodies by B-cells. Even though the two responses are mostly involved in the clearance of parasites with different ecological niches (intracellular vs. extracellular parasites), and although effectors of the Th1 response tend to have inhibitory effects on the Th2 response and vice versa, the two responses can also operate in concert to eliminate different stages of the same parasite exploiting different tissues. The dichotomy between innate and adaptive immunity is also quite artificial since innate and adaptive effectors do strongly interact to determine the issue of the interaction between the host and the parasite.

A Th2-type response induced by the activation of CD4⁺ T cells is the predominant mechanism of clearance of helminths. Studies on mice infected with gastrointestinal nematodes, such as *Heligmosomoides polygyrus* or *Trichuris muris*, have shown that Th2 cytokines (IL-4) are essential for a rapid expulsion of adult parasites from the gut. It should nevertheless be noted that other gastrointestinal nematodes might require the activation and production of other cytokines, such as IL-13, to be cleared and certainly there exists synergistic effects due to the interactive effect of different cytokines. These synergistic effects are nicely illustrated by studies where genes of different cytokines have been simultaneously knocked down.

Another interesting aspect of nematode infection is that they tend to persist over long period of time in humans and animal hosts. Chronicity of infection is generally due to the inhibition of the Th2 response by two different mechanisms. In certain cases, it has been shown that infection with *Trichuris muris* leads to a Th1 response that is beneficial to the parasite because it inhibits the most threatful Th2 response. Under natural conditions, hosts are exposed to a range of micro and macroparasites that elicit different branches and types of the immune response. It is therefore possible that microparasite infections that lead to a Th1 response set a favorable ground for the establishment of helminth infection. An alternative pathway by which gut nematodes might achieve to persist into the host for long periods of time involves the specific down-regulation of Th2 cytokines by regulatory cytokines such as IL-10 and TGF- β . A fascinating observation is that helminths produce mimics of these regulatory cytokines to manipulate the host immune system for their own benefit. This capacity of many parasite species to overrule the host immune system will be briefly treated in the following section.

Immune subversion

By definition, a successful parasite is a parasite that manages to complete its life cycle and to transmit to a novel host. To achieve this goal, parasites have to go through the selective filter that represents the immune system. A parasite that is recognized and killed by the immune effectors will have nil fitness and would not be able to establish a persistent infection. Therefore, there exists quite strong selection pressure to promote mechanisms that allow parasites to subvert the host immune system.

Parasites can subvert the host immune system using strikingly diverse pathways. They can interfere with the very early stage of immune recognition, they can block complement, avoid phagocytosis, escape vacuoles, interfere with antigen presentation, hide and become invisible to the immune system by coating their surface or change identity by expressing different sets of surface proteins (antigenic variation) (Sacks and Sher, 2002). Finally, some parasites can directly down-regulate the host immune response by stimulating the production of anti-inflammatory and regulatory cytokines (IL-10 and TGF- β) or even by producing mimics of these regulatory cytokines.

Antigenic variation has been reported for many protozoa that induce disease in humans. Among the best-known examples are *Trypanosoma* and *Plasmodium*. Trypanosomes escape the humoral immune response by coating the entire cell surface with a very dense layer of glycosylphosphatidylinositol (GPI)-anchored variant surface glycoprotein (VSG). During the infection, VSG express intense antigenic variation since different VSG genes are transcribed during the course of the infection. Although only one VSG gene is expressed at time, the pool of genes is fairly large and switches from one gene to another are relatively frequent. Therefore, during the course of the infection, new antigenic variants emerge and even though B-cell clones can keep track of the most prevalent antigenic variant, the emergence of new variants allows the persistence of the infection in the face of the host immune response.

A similar phenomenon has been described for *Plasmodium* parasites that express very variable surface proteins (*var*). As for trypanosomes, *Plasmodium* expresses different *var* genes during the course of the infection and therefore antibodies produced at a given time are effective to attack the most predominant variant but cannot keep track of the newly emerged variants.

Rodent malaria (*Plasmodium yoelii*) has also been shown to activate a specific family of T lymphocytes that have a regulatory function (Hisaeda et al., 2004). Treg cells are characterized by the CD25⁺ receptor and account for 5–10% of peripheral CD4⁺ T cells in mouse and humans. Treg cells contribute to ensure self-tolerance by suppressing auto-reactive lymphocytes, mostly through contact or via the secretion of anti-inflammatory cytokines, such as IL-10 and TGF- β (Belkaid, 2007). However, parasites might take advantage of these regulatory mechanisms for their own benefit.

Helminths are masters in the down-regulation of the immune response of their host (Maizels, 2005). Helminths usually occur with high prevalence in natural populations. In many instances, the infection persists in face of the host immune response, suggesting that helminths have evolved effective strategies of immune evasion and suppression. Adult helminths often survive within immunocompetent hosts by inducing immunoregulatory mechanisms involving regulatory T cells that result in a shift towards an anti-inflammatory environment characterized by high levels of anti-inflammatory cytokines. The hypo-responsiveness of the immune system prevents the elimination of the worm, but can also protect the host against excessive inflammation. *Heligmosomoides polygyrus*, a rodent nematode phylogenetically close to the human hookworms, has been shown to drive the differentiation of Treg cells from naïve CD4⁺ T cells by secreting a product that binds to host TGF- β receptors. Tregs appear to be

involved in the long-term establishment of infection with *Litomosoides sigmodontis*. Susceptible strains of mice are able to clear the infection when Tregs are experimentally removed.

Tregs also play a role in the dampening of Th2 response in humans infected with helminths. In some African populations, people carrying a schistosome infection have higher numbers of circulating Tregs compared to people who do not carry the infection. Interestingly, there might be a certain degree of heterogeneity in the potential of Tregs to shut down the immune response and this heterogeneity might be partly due to an active role of helminths. In agreement with this hypothesis, it has been shown that Tregs isolated from people carrying helminthic infections were more effective in reducing TNF- α production upon stimulation with *Plasmodium* antigens.

Immunopathology

Although the immune system is an essential component of organismal homeostasis involved in both parasite protection and surveillance of malignant cells, it can also represent a serious threat for the host structures (cells and tissues). To be effective the immune system has first to make a distinction between self and non-self. To achieve this task the immune system has central and peripheral control mechanisms. Negative selection of auto-reactive T-cell clones in the thymus and suppression of auto-reactive T-cells that have escaped the thymic filter are examples of the two types of control. In addition to avoiding self-recognition, the immune system has to keep control of an over-reactive response. Over reactive inflammatory responses can be particularly threatening because they do not rely on a specific recognition of self/non-self. Oxidative burst, production of cytotoxic compounds, cytokine storms, septic shock are a few examples of potentially very harmful side effects of the inflammatory response. Actually, immune disorders are now common diseases in western societies where the incidence of these autoimmune diseases has increased in a very substantial way during the last decades (Bach, 2002). In addition to autoimmune diseases, the immune system has been identified as representing a component of the most severe symptoms induced by some of the major infectious and parasitic diseases. Among the 10 most important tropical infectious diseases recognized by the WHO, all of them have an immunopathological component (Graham et al., 2005). For instance, the most severe symptoms of human malaria (cerebral malaria) are due to uncontrolled inflammatory response (van der Heyde et al., 2006). Similarly, uncontrolled immune response increases skin lesion and liver damage during the *Leishmania* infection and unregulated response damages the central nervous system in trypanosome infection. Therefore, unregulated immune response is an additional component of pathogenesis of most parasitic diseases (Sell, 2001).

Parasites that attenuate the immune response have, therefore, the potential to reduce the severity of infection where the symptoms are due to a dysfunction of the immune response (Sorci et al., 2013). In line with this argument, murine cerebral malaria induced by *Plasmodium berghei* is ameliorated by the inoculation of the filarial parasite *Brugia pahangi* (Yan et al., 1997) and the serum of *Heligmosomoides polygyrus*—*Plasmodium chabaudi* co-infected mice has lower concentration of pro-inflammatory (IFN- γ) and higher concentrations of anti-inflammatory cytokines (IL-10 and TGF- β) than *Plasmodium chabaudi*-infected mice. In humans, increased levels of pro-inflammatory cytokines associated with cerebral malaria are down regulated by a concomitant infection with the nematode *Ascaris lumbricoides* (Nacher et al., 2000). Again, the protective effect is due to the activation of regulatory T-cells and the secretion of high levels of IL-10 and TGF- β induced by *Ascaris lumbricoides* infection.

Autoimmune disorders are not exclusively produced by an ongoing infection. A noticeable proportion of cancers appear as the outcome of excessive inflammation and many other age-related diseases have an inflammatory origin (Coussens and Werb, 2002). Here, again, infection with parasites that rely on the dampening of immune reactivity for their own persistence within the host can provide the host with a benefit in terms of protection towards risk of lethal autoimmunity.

As for the reduction of disease severity, parasites seem to play a key role in the protection from autoimmunity (Table 1). Under certain circumstances, parasites that down-regulate the immune response might contribute to reduce the risk of autoimmune diseases or possibly alleviate the symptoms of the disease (Table 1). There are several epidemiological and experimental reports showing that infection with helminths is negatively correlated with the incidence of several autoimmune disorders (Dunne and Cooke, 2005). For instance, experimental infection with the trematode *Schistosoma mansoni* prevents the development of Type-1 diabetes mellitus in non-obese diabetic mice (Cooke et al., 1999), as well as allergic encephalomyelitis and Grave's thyroiditis. Intestinal nematodes, such as the murine parasite *Heligmosomoides polygyrus*, have also been shown to have immunomodulatory properties. Mice with chronic *Heligmosomoides polygyrus* infections are less likely to develop airway inflammation and allergy (Wilson et al., 2005). Finally, infection with *Litomosoides sigmodontis* reduces the risk of becoming diabetic in NOD mice.

Resistance vs. tolerance

Host immunity is often seen as a mechanism conferring either protection against parasitic infection either allowing the host to kill the intruder as fast as possible. Immune effectors that allow clearing the infection (killing the parasite or limiting its proliferation) make the host resistant to that particular parasite. However, as already mentioned above, immunity also confers costs in terms of overreacting or misdirected responses. An alternative strategy that might produce higher fitness rewards, might be to minimize the cost of the infection, or in other words to tolerate the infection (Soares et al., 2017). Contrary to resistance, tolerance mechanisms do not aim at hitting the intruder, but instead at limiting the damage it induces. Tolerance to infection has now been investigated in several species, and to this purpose, helminths have proved be particularly useful model systems. As already said, helminths are

Table 1 A non-exhaustive list of parasites (protozoa and helminths) that have been reported to protect from autoimmune diseases.

large metazoan and several species migrate through the body of the host, causing tissue damage. Interestingly, the canonical type-2 response that characterizes helminth infection also plays a key role in tissue healing and repair. Therefore, it has been suggested that a polarized type-2 response during a helminth infection might contribute to limit the cost of the infection by restoring tissue integrity (Gause et al., 2013). In addition to this, the activation of regulatory pathways and anti-inflammatory cytokines, that are both under host and parasite control, also contributes to tolerance (King and Li, 2018).

The bacterial world is a universe that we are just beginning to understand. Until a few decades ago, our view of the bacterial world was limited by the technology available to study it, and in many aspects, it had changed relatively little in the last century. Our vision was basically limited to cultivable bacteria, when today we know that this is a probably a very minority group of the total. Now we know that we have managed to cultivate bacteria belonging to just 30 *phyla*, of which 95% belong to four *phyla* (*Firmicutes*, *Bacteroidetes*, *Proteobacteria* and *Actinobacteria*), when the List of Prokaryotic Names with Standing in Nomenclature (LPSN) recognizes more than 40 *phyla*, and the SILVA database recognizes around 90.

Bacteria are prokaryotic cells. Prokaryotic cells are those that lack a proper nuclear membrane and lack membrane-bound organelles such as endoplasmic reticulum, Golgi complex or mitochondria. There are two kingdoms of the six into which living beings are divided, made up of prokaryotic cells: *Eubacteria* and *Archaea*.

Though *Archaea* are microorganisms that have been associated habitually to extreme conditions of life of temperature, salinity, pH, etc. (extremophiles) they can also be found in environments where it is more likely to interact with other living organisms. However, no microorganisms belonging to the *Archaea* Kingdom have been described by now that cause or are associated to diseases in animals or plants. Thus, in this chapter we will refer only to *Eubacteria*, since it is the Kingdom that integrates all prokaryotes (bacteria) pathogenic for humans and animals.

Although bacteria are mostly microscopic organisms, their size is highly variable. While the bacteria most frequently isolated as members of the normal human microbiota, or as causing infections in humans, measure a few microns (staphylococci about $1 \times 1 \mu\text{m}$, enterobacteria about $1 \times 2 \mu\text{m}$), and therefore are clearly microscopic organisms, some bacteria are even at the limit of visibility without the need for a microscope, such as *Epulopiscium fishelsoni*, a large, symbiotic bacteria found within the intestinal tracts of some species of tropical surgeonfish (Family *Acanthuridae*), or are directly visible with the naked eye, such as *Thiomargarita namibiensis*, a chemolithotrophic bacterium that is capable of using the nitrate anion as a terminal electronic acceptor in the electronic transport chain, and that is capable of storing high concentrations of nitrate in a massive vacuole, which is responsible for 98% of its size. Anyway, as a rule they are smaller than eukaryotic cells. As an example, *Escherichia coli*, one of the most abundant bacteria in the intestine of many mammals, measures approximately $1 \times 2 \mu\text{m}$, while a hepatocyte can have a diameter between 25 and 40 μm .

From a morphological point of view, bacteria are grouped into **cocci** (bacteria with approximately round or oval morphology), **bacilli** (elongated, approximately cylindrical morphology), **vibrio** (curved, comma-shaped microorganisms), **spirillum** (rigid helical morphology), **spirochetes** (flexible helical morphology, which gives them a characteristic undulating movement). In addition, it must be considered that this “basic” morphology can be modified by other factors such as the presence of spores, which can sometimes noticeably deform the bacterial cell (Fig. 1).

Bacteria divide by binary fission, as we will see in detail later. However, the division of the wall in some bacterial genera and species tends to be incomplete, which makes these bacteria, not completely separated, appear forming characteristic groups. Thus, cocci can appear grouped in pairs (**diplococci**), as frequently happens in *Streptococcus pneumoniae* or *Neisseria*, in chains (**streptococci**), in cubic structures (**tetrads**) or in irregular groupings, which have classically been morphologically compared to bunches of grapes (**staphylococci**), hence its name, from the Greek *staphylé*, bunch. **Filamentous bacteria** are bacilli that remain attached end to end when divide, thus leading to long filaments composed by several individual bacilli (Fig. 2).

Fig. 1 Bacterial morphologies.

Fig. 2 Types of bacterial aggrupation.

As mentioned in the previous paragraph, bacteria divide by **binary fission** (Fig. 3). The division of eukaryotic cells poses two problems from a biological point of view. It is necessary to duplicate a DNA present in large quantities, and grouped in complex structures, the chromosomes, and it is necessary to duplicate all the organelles, especially membrane-covered organelles. Bacteria, however, do not have membrane-covered organelles to duplicate, and they have a much smaller amount of DNA (between 1000 and 2000-fold smaller) than eukaryotic cells, allowing directly to duplicate DNA and divide the cell, generating two new cells, each of which contains one of the DNA copies. This simplicity of replication conditions another of the characteristics of bacterial division, which is speed. *E. coli* can replicate, in optimal conditions, every 20 min. In more real conditions, its replication time can be around an hour. Still, this means that each individual *E. coli* cell would have generated, within 24 h, between 15 and 20 million of new bacteria.

Although it has important differences with eukaryotic cells, prokaryotic cells also have some characteristics in common with them. They are covered by a cytoplasmic membrane that allows them to maintain a stable environment in terms of its characteristics

Fig. 3 Binary fission.

(composition, pH, etc.) inside. They also have a genetic endowment based on DNA, and a protein synthesis machinery (mRNA, tRNA, ribosomes) functionally like that of eukaryotic cells, although structurally the ribosomes show differences that, i.e., are responsible for selective toxicity (toxicity for bacteria but not for eukaryotic cells) of various groups of antimicrobials (macrolides, aminoglycosides, tetracyclines, among others).

The lack of an endomembrane system means that the bacteria do not have specialized spaces to carry out specific functions, so that all reactions must be carried out in the cytosol.

Bacterial genome

Biological information in bacteria follows the universally accepted paradigm. The basic unit of genetic information is the **gene**, which codes for the amino acid sequence of a protein. Genes are grouped primarily in **chromosomes**, but also in other **genetic elements**, and the set of all genetic elements constitutes the **bacterial genome**. This way, bacterial genome is the whole genetic information of a microorganism, and is formed by the genes that encode proteins, the RNA and regulatory sequences, as well as all the non-coding DNA that may be present.

We can divide the genome into the following types:

- Bacterial genome is made up of the total set of genes that a bacterium possesses and comprises both its chromosome and all the extrachromosomal genetic elements, if any.
- Genome core is formed by the set of genes present in all individuals of a specific bacterial species.
- Accessory genome which is the set of variable genes between members of the same species.
- Metagenome that is reserved to refer to the set of genes of microbial origin present in a ecosystem.

As in other living organisms, genetic information is stored in **DNA**, which is translated into **messenger RNA (mRNA)** by RNA polymerases. This mRNA will be the one that, in ribosomes, directs protein synthesis and establishes its exact amino acid sequence. For its part, the **transference RNA (tRNA)** will be the one that, following the instructions of the mRNA, incorporates each amino acid in the corresponding position into the ribosome, to give rise to the synthesis of the complete protein.

The main genetic elements in bacteria are the **chromosome** and **plasmids**.

Most bacteria contain a single circular chromosome, although some specific species may contain two and up to three chromosomes.

Plasmids are linear or circular DNA strands, usually much smaller than the chromosome, with the ability to replicate independently of the chromosome. They can be transferred from one bacteria to another directly (conjugation) or through phages (transduction).

Transposable elements are DNA fragments integrated into other DNA molecules (plasmids, chromosomes ...) but that can move within the same DNA molecule, or to another DNA molecule.

Furthermore, some bacteria can capture free bacterial DNA in the medium and integrate it into their own genome (**transformation**). Some human pathogens, such as *S. pneumoniae*, have a particularly marked ability to take up DNA in this way.

Both plasmids, transposable elements and transformation have been shown in recent years as decisive elements in the horizontal transmission of different characteristics of microorganisms, including antimicrobial resistance. Thus, plasmids and transposable elements are decisive elements in the horizontal transmission of resistance to antimicrobials, and transformation has also been shown to be an efficient way to develop resistance in pneumococci, through the uptake by transformation of DNA from streptococcal species more resistant to penicillin.

Plasmids and transposable elements are decisive elements for the genetic variability of bacterial populations. While the semi-conservative reproduction of eukaryotic organisms guarantees recombination and sufficient genetic heterogeneity in populations, bacterial reproduction by binary fission implies that the new bacteria are identical copies of the previous one. This would suppose, without corrective elements, a genetic homogeneity in the bacterial populations that would be very dangerous for the

survival of the species in the event of any alteration in the habitat conditions. These genetic elements, which reproduce independently of the chromosome, are also transmitted independently of it and are capable of transposing with great freedom between some major genetic elements and others, represent an element of genetic heterogeneity that is vital, in the long term, for the survival of the species.

The bacterial chromosome is integrated into a structure called the **nucleoid**. The lack of a proper nucleus is one of the basic characteristics that differentiates prokaryotic cells from eukaryotes. The nucleoid is an area within the bacterial cell that groups most of the bacterial genome, particularly the chromosome, but is not delimited, as in eukaryotic cells, by a cell membrane. The composition of the nucleoid is at least 60–70% DNA. The rest are mainly mRNA and proteins with different functions. This includes both proteins responsible for regulating the transcription of certain genes, and proteins helping to maintain the supercoiled structure of the nucleic acid (**nucleoid proteins** or **nucleoid-associated proteins**). These nucleoid proteins are distinct from histones of eukaryotic cells. While in eukaryote DNA is wrapped around a histone protein core, the nucleoid DNA-binding proteins do not form nucleosomes. Instead, they often use other mechanisms, such as DNA looping, to promote compaction.

Ribosomes

Ribosomes are particles made up of ribosomal RNA (rRNA) and proteins, and are the place where protein synthesis takes place, therefore it is a fundamental element for living beings. The ribosome is responsible for reading the sequence of the messenger RNA and through the genetic code it translates the base sequence of the messenger RNA into a specific amino acid sequence.

We can find ribosomes in mitochondria, cytosol, chloroplasts, and endoplasmic reticulum. They are small and therefore can only be viewed under an electron microscope. They have no membranes in their structure.

Ribosomes are made up of subunits that are named through the sedimentation coefficient in Svedberg units (S). It indicates the relationship between the sedimentation speed of a particle and the applied acceleration that causes the sedimentation.

Ribosomes are dynamic structures, and their subunits associate and dissociate alternately and will also interact with other proteins.

Prokaryotic cells have ribosomes with a 70S sedimentation coefficient and in turn it is divided into two subunits:

- The largest subunit (L subunit) that has a 50S sedimentation coefficient and contains 5S and 23S rRNA and 31 proteins.
- The minor subunit (S subunit) that has a 30S sedimentation coefficient and contains 16S rRNA and 21 proteins.

Eukaryotic cells have a sedimentation coefficient of 80S. They are also made up of subunits:

- The largest subunit that has a sedimentation coefficient of 60S and contains 5S 28S 5.8S rRNA and 49 proteins.
- The minor subunit that has a 40S sedimentation coefficient and has a single 18S rRNA molecule and 33 proteins.

Although the functions of ribosomes are similar in eukaryotic and prokaryotic cells, their structures, although similar, present crucial differences. These structural differences are those that confer selective toxicity to some of the main groups of antibiotics (aminoglycosides, tetracyclines, chloramphenicol, macrolides...) allowing them to inhibit bacterial protein synthesis without significantly interfering with protein synthesis in prokaryotic cells.

Cell envelope

The cell envelope is formed by a group of structures surrounding the cytoplasm. These structures have several crucial functions: they are involved in attachment to biological and inert surfaces, can protect the microorganisms from the action of the immune system, protect the bacteria from mechanical stress and has have a decisive role in the exchange of substances with the environment.

Cytoplasmic membrane

Unlike other structures, such as the cell wall, the cytoplasmic membrane is highly conserved in all bacteria, and bears great similarities to the cytoplasmic membrane of eukaryotic cells. Its main function is to act as a semi-permeable selective membrane, which allows or not the passage of different molecules. However, its structure incapacitates it, due to its almost semi-liquid consistency, to act as a barrier or physical protection, as occurs with the wall.

The cytoplasmic membrane of both prokaryotic and eukaryotic cells is made up of a phospholipid bilayer, organized in such a way that the hydrophobic lipid parts are oriented inwards, and therefore contiguous, while the polar parts are oriented outwards, therefore in contact with the external environment on one side, and with the cytoplasm on the other. Proteins appear integrated, to a greater or lesser extent, in the cytoplasmic membrane. These proteins can be attached loosely to the outer part of the cytoplasmic membrane (peripheral proteins), embedded more extensively in it (integral proteins) or completely cross the cytoplasmic membrane (transmembrane proteins). These proteins play an important role in different cellular processes crucial for the bacteria, such as energy production and transport. (Fig. 4).

Fig. 4 Cytoplasmic membrane. Structure.

The characteristics of the cytoplasmic membrane make it an effective barrier that prevents the free diffusion of substances between the inside and outside of the cell. Thus, most of the substances must enter and leave the cell through transporter proteins. This system not only guarantees a selective transport into and out of the bacteria, but also allows substances to accumulate against a concentration gradient, thus ensuring an adequate intracellular concentration of the different compounds necessary for bacterial metabolism, regardless of its concentration in the external environment. These carrier proteins can be highly specific for certain compounds or have a broader range of substrates.

These transport systems require energy. The cytoplasmic membrane is also a point of energy production. The accumulation of protons on the outside of the membrane generates an electrochemical potential difference between the inside and outside of it. This potential difference (proton motive force) is used by the cell for different functions, such as transport against a gradient, the movement of flagella that confers mobility to the cell or the production of high-energy molecules, such as ATP.

Cell wall

The high concentration of solutes inside the bacterial cell leads to a high intracellular osmotic pressure (around 2 atm). This pressure would cause the bacterial cell to burst, if it did not have a rigid cover, which does not exist in eukaryotic cells, which is the cell wall. The cell wall is also responsible for maintaining bacterial morphology.

The bacterial wall can be structured in two clearly differentiated ways: the Gram positive wall and the Gram negative wall, named for their different behavior with the staining method devised in the 19th century by the Danish microbiologist Hans Christian Joachim Gram.

The Gram positive bacterial wall is almost exclusively made up of a thick layer of a polysaccharide compound called peptidoglycan, while the more complex Gram negative wall is made up of several layers with different composition, only one of which contains peptidoglycan. Although most bacterial families have a cell wall, there are some families, such as the *Mycoplasma-taceae* family, that naturally lack this structure.

Structure of the cell wall. Peptidoglycan

Peptidoglycan is a polysaccharide compound that is present in all bacterial walls, both Gram positive and Gram negative, and is what confers rigidity and resistance to the wall. It has a central structure made up of the alternative repetition of two polysaccharide molecules, *N*-acetyl-muramic acid and *N*-acetyl-glucosamine, linked by a β -1,4 bond. Attached to each residue of *N*-acetyl-muramic there is a tetrapeptide that can vary discretely from one microorganism to another (Alanine-Glutamic Acid-Lysine-Alanine) or (Alanine-Glutamic Acid-diaminopimelic Acid (DAP)-Alanine). These peptidoglycan chains, which extend longitudinally throughout the cell, establish covalent bonds with the adjacent ones through these tetrapeptides, between the third amino acid of one of them (lysine or DAP) and the fourth of the adjacent one (alanine), either directly or through a glycine pentapeptide, as occurs for example in staphylococci. In this way, a large macromolecule is formed that covers all the bacteria (Fig. 5).

The peptidoglycan thus formed constitutes a sufficiently strong and stable structure to withstand the high intracellular osmotic pressure and avoid osmotic lysis of the cytoplasmic membrane.

Fig. 5 Peptidoglycan structure.

Cell wall. Gram positives

The cell wall of Gram positives is considerably thicker than that of Gram negatives and is more than 90% made up of overlapping layers of peptidoglycan.

The remaining 10% is largely made up of glycerol phosphate or ribitol phosphate compounds, embedded in peptidoglycan and generically called teichoic acids, if they are covalently bound to the peptidoglycan, or lipoteichoic acids, if they are bound to the cytoplasmic membrane. (Fig. 6).

Cell wall. Gram negatives

The Gram-negative wall has a much lower amount of peptidoglycan, generally formed by a single layer of the polysaccharide compound, that is included in the so-called periplasmic space, limited by the cytoplasmic membrane on the inside and the outer membrane on the outside. This outer membrane, which does not appear in Gram positives, is a second phospholipid bilayer external to the peptidoglycan, which contains associated proteins, like the cell membrane, but also contains polysaccharides associated with the lipids of the bilayer, therefore it is also commonly referred to as a lipopolysaccharide (LPS) (Fig. 6).

Laurent, E. (2016, December 31). Bacterial cell wall. OER Commons. Retrieved October 27, 2021, from <https://www.oercommons.org/authoring/19267-bacterial-cell-wall>.

Fig. 6 Structure of Gram-positive and Gram-negative wall.

The outermost layer of LPS is composed of polysaccharides and consists of core polysaccharides and O-specific polysaccharides, frequently branched. The innermost part of the lipopolysaccharide is lipid A, which is associated with the outer layer of the phospholipid bilayer and harbors the endotoxic action of Gram-negative LPS.

This outer membrane is an impermeable structure, so most of the substances must penetrate through specific pathways. These pathways are mainly the so-called **porins**, transmembrane proteins made up of three identical peptides, which form aqueous channels through which polar substances can pass through the LPS. There are **nonspecific porins**, through which numerous compounds can penetrate, especially small hydrophilic compounds, without any structural relationship, and **specific porins**, which show binding sites for specific compounds, or groups of compounds structurally related, which will be the only ones capable of penetrating. Through that channel.

The LPS is separated from the cytoplasmic membrane by a space, called the **periplasmic space**, which houses the thin layer of peptidoglycan present in this type of bacteria. This periplasmic space houses different structures and molecules important in the physiology of the microorganism and shows an important metabolic activity. The LPS is anchored to the peptidoglycan through lipoproteins that join both structures crossing the periplasmic space: they are the so-called Braun lipoproteins.

In this periplasmic space, a metabolically very active area, proteins with various functions are found, from hydrolytic enzymes to proteins with transport functions, or synthesis of extracellular structures, such as penicillin binding proteins (PBP), proteins involved in the final phases of peptidoglycan synthesis, and target of beta-lactam antibiotics.

Pili and fimbriae

Pili are thin, hair-like appendages found on the surface of bacteria. Short pili, especially adapted to mediate adherence functions are also called **fimbriae**. They are usually more numerous than pili. Both are filamentous proteins and can fulfill many functions. They facilitate adherence to surfaces, allow the formation of biofilms, and can be a fundamental factor of virulence by mediating adherence to animal tissues.

Some pili have specific functions beyond adherence. This way, **conjugative pili** facilitate the genetic exchange between bacteria through a process called **conjugation**.

This process of bacterial conjugation serves to transfer genetic information from a donor cell to another recipient, involving plasmids and specialized surface structures with specific functions such as pili.

Pili are characteristic of Gram-negative bacteria. In fact, virtually all Gram-negative bacteria produce pili of one type or another but can also be found in Gram positive microorganisms.

Another type of pili are **electrically conductive pili** or **nanowires**. These pili are capable of establishing a flow of electrons from or to a specific cell, thus having an important role in energizing the affected cells.

Finally, **type IV pili** are capable not only of establishing adhesion functions, but of giving rise to a special type of bacterial movement called *twitching motility*, that allows bacteria to move along a surface by extension, adhesion to the surface and retraction of this type of pili. These filaments are thin and flexible but have great mechanical strength. They can appear at one or both poles of the bacteria individually or in groups. They are also the most frequently found in both Gram positive and Gram negative bacteria.

In addition, these type IV pili play a role in the infectivity of different human pathogens (*Neisseria gonorrhoeae*, *Streptococcus pyogenes* . . .), by allowing them to move on the epithelial surfaces to locate the most suitable place to start the infection. This class of pili are subdivided into two groups, IVa and IVb, based on the major subunit of pilin that makes them up.

The motility mediated by these pili is independent of that produced by flagella, and occurs on solid surfaces. This movement can be described as jerking or jumping. The correct retraction of these structures allows them to get closer and to adhere to the host cell, achieving greater stability.

Capsule and slime

Many bacteria produce substances external to the cell wall, usually of a polysaccharide and sometimes protein composition, which form a kind of external envelope for the bacteria, with functions of physical and mechanical protection, adherence, and defense against various external factors (phagocytosis, antibodies. . .). It tends to be called a **capsule** when it is a more individualized covering, tightly attached to the bacteria and readily visible with light microscopy, and **slime** when it tends to form a matrix more loosely attached, that usually can't be seen by light microscopy and includes larger groups of bacteria.

One of their main functions is adherence. Many pathogens, to colonize and invade an organism, need to adhere to certain cell surfaces. This union, at least in its initial stages, is usually done non-specifically through these structures. Later this binding can be made more specific through the interaction between certain structures of the bacterial surface and specific receptors.

The capsule also plays an important role in protection against the immune system. The presence of a capsule makes it difficult for phagocytes to engulf the bacteria and the interaction of antibodies with specific epitopes of the bacterial wall. The importance of the capsule is evident in cases such as *S. pneumoniae* or *Haemophilus influenzae*. In the first case, the capsule is a determining factor for the pathogenicity of the microorganism, so that, in the absence of the capsule, *S. pneumoniae* virtually loses its invasive potential. In the case of *H. influenzae*, the presence of a capsule, especially capsular type B, is crucial for the organism to be capable of producing serious invasive infections, such as bacteraemia, meningitis, or epiglottitis. (Fig. 7).

From W.H. Taylor and E. Juni, "Pathways for Biosynthesis of a Bacterial Capsular Polysaccharide," *Journal of Bacteriology* (May 1961)

Fig. 7 Bacterial capsule.

These structures are also decisive in the ability of bacteria to bind to inert surfaces, giving rise to structures called biofilms, which consist of groups of bacteria firmly attached to each other and to inert surfaces by means of this *slime*. This adherence is important in the biology of many pathogenic bacteria and the pathogenesis of the infections caused by them. Thus, the biofilms that *Legionella* forms on the surface of pipes, water pipes, etc., have a decisive role in maintaining the colonization of these structures and, eventually, in that these colonized structures behave as a source of microorganisms that eventually they can pass to man and cause infection. Similarly, the ability of some microorganisms to form biofilms in prosthetic materials used in medicine (catheters, orthopedic prostheses, cardiac prostheses ...) play a fundamental role in infections associated with this type of devices.

Cell movement. Flagella

Some cells can move within liquid media, or even along the surface of solid media, thanks to rotating structures capable of propelling them, called flagella. They are elongated structures, attached to the cell at one end and free at the other end, which can be single or multiple, and present several forms of association:

- *Monotrichous*—Bacteria have one only polar flagellum.
- *Lophotrichous*—All flagella are grouped at one cell end.
- *Amphitrichous*—Bacteria have two tufts of flagella grouped at both poles.
- *Peritrichous*—Bacteria present flagella distributed throughout its perimeter (Fig. 8).

The flagella are too thin to be observed by conventional stains, but there are specific stains that allow them to be observed. Obviously, they can also be observed by electron microscopy.

The flagella have a rotary motion, similar to that of a ship's propeller, and are capable of moving in both directions, and therefore propel the bacterium forward or backward. This movement is obviously carried out with a consumption of energy, which is provided by the proton motive force. The flagella do not have a fixed rotational speed, but this mobility is modulable, reaching a maximum of about 1000 rpm, which implies a mobility for the bacteria of 100–120 $\mu\text{m/s}$. To evaluate this mobility in real terms, we must understand that this speed implies moving a length equivalent to 50–60 times its own length in 1 s. If we applied this same parameter to a 4 m long car, this would mean traveling at about... 800 km/h!

Flagella are protein structures. The free part of the flagellum, called the *filament*, is made up entirely of a protein called *flagellin*. There are also a series of structures related to its anchorage to the bacterial wall and to the energization of the process, which constitute the motor of the flagellum. It is a central rod surrounded by a series of discs, attached to the filament through a proteic area called *hook*. In Gram negatives, there are several discs: a disc called *L disc*, anchored to the LPS, a second, more internal disc, denominated *P disc*, anchored to peptidoglycan, an *MS disc*, anchored to the cytoplasmic membrane, and a *C disc*, included within the cytoplasm. Gram positive bacteria lack the outer (L and P) discs, and only the inner discs (MS and C) are found.

Outside the internal discs, and anchored to the cytoplasmic membrane and peptidoglycan, a structure called *stator* appears, formed by a protein called *Mot*, and whose mission is to provide torsional force. It would be the device that would facilitate the energization of the turbine, which is ultimately the entire base of the flagellum, through the proton motive force. The translocation of protons through channels present in this structure would generate the energy necessary to rotate the internal discs, and consequently the flagellum (Fig. 9).

Motility, even though it is not a vital characteristic for the bacteria (there are immobile bacteria), confers great advantages on being able to move towards optimal areas from the nutritional point of view, temperature, pH, etc. On the other hand, this motility is important in the pathogenicity of some bacteria. Thus, the motility conferred to *Helicobacter pylori* by its polar flagellum, allows it to migrate rapidly towards the gastric wall and penetrate it, minimizing the time of exposure to gastric pH, and thus facilitating its survival.

Endospores

Endospores are forms of bacterial resistance capable of surviving in extreme conditions. They must be differentiated from **spores**, which are active reproductive structures produced mainly by fungi, some plants, and some bacterial genera, such as *Streptomyces*.

Endospores are not reproductive structures. They are highly differentiated, dormant cells, which can withstand very unfavorable conditions such as extreme temperatures (they can survive for hours in boiling water), aggressive chemicals, radiation, dryness, or lack of nutrients. Endospores are a reversible status in bacterial cycle life. A vegetative form can convert to an endospore when environmental conditions are unfavorable to it, and this endospore can in turn revert to a vegetative form when conditions become favorable again. Not all bacterial species can produce endospores. It is a characteristic that is more common in bacteria whose habitat usually gives unfavorable conditions for the bacteria (high or low temperatures, droughts, high irradiation . . .) in a cyclical way, so the bacteria must be prepared to resist in these conditions, and to be able to return to the vegetative form when the situation

Juan Luis Muñoz Bellido, personal collection.

Fig. 10 Sporulated clostridia in a mixed infection.

allows it. In fact, only two bacterial orders are known, the order *Bacillales* and the order *Clostridiales*, capable of producing endospores. Among them, the two most frequent genera in human infections are the genera *Bacillus* and *Clostridium*, and in the main human diseases caused by microorganisms of these genera (anthrax, caused by *Bacillus anthracis*; botulism, caused by *Clostridium botulinum*; tetanus, caused by *Clostridium tetani*; gas gangrene, caused mainly by *Clostridium perfringens* among others), the ability to sporulate is a decisive factor in its infective cycle (Fig. 10).

On the other hand, they are extremely long-lived biological forms, since they can survive for hundreds of years, and can be easily spread by wind, water and through animal stools.

Endospores are refractive structures in the light microscope, and they do not stain with conventional methods, so they often appear within cells as unstained areas. However, they can be dyed with specific procedures, such as Schaeffer-Fulton's method, also known as malachite green staining.

The process that leads to the formation of endospores is called **sporulation**.

In the process of sporulation, vegetative cells will become non-growing structures that resist heat and are light-refractive. The sporulation process is usually triggered when growth stops because one of its essential nutrients is depleted.

In turn, this is a reversible process since they can remain dormant for years and easily revert to a vegetative cell through a process called **germination**. In the same way that sporulation is triggered by the absence of certain essential nutrients, germination is precipitated by their availability. This process consists of three phases: **activation**, **germination** and **outgrowth**.

During the **activation phase**, the endospore rehydrates, losing its resistance to heat and chemicals, and becoming less refractile under the microscope. During the **germination phase** it loses the structures characteristic of the endospore and recovers the typical structures of the vegetative cell and finally, during the **outgrowth phase**, it fully recovers the functionalities of a vegetative cell and begins to divide by binary fusion. This can be a very fast process that, if the circumstances are favorable, can be completed in a few minutes.

The endospore has a series of chemical components and structures absent in the vegetative cell. From the inside out, it is made up of an internal area or **core**, which contains DNA and ribosomes from the cytosol of the vegetative cell. Immediately outside there is an **inner membrane**, which develops from the cytoplasmic membrane of the vegetative cell, the **cortex**, which is made up of peptidoglycan also from the vegetative cell and an **outer membrane** that, unlike the previous layers, is formed during the sporulation phase. Outside is the **endospore coat**, made up of endospore-specific proteins. A final, inconsistent protein layer may exist, which is not present in all cases, called **exosporium**.

There are two key compounds for endospore resistance characteristics, which are dipicolinic acid and calcium. Dipicolinic acid is a characteristic component of the endospore and can account for up to 15% of its total weight. Dipicolinic acid, inside the core, combines with calcium, giving rise to **calcium dipicolinate**, which binds to free water in the core, producing intense dehydration (the endospore has approximately 25% of the water present in the cell vegetative). This dehydration inactivates the existing enzymes in this area, which, however, are not denatured, so that they can be reactivated when the endospore rehydrates and germinates. In addition, calcium dipicolinate is capable of intercalating between the bases of DNA, stabilizing its structure.

Another important component of the endospore are the so-called **small acid-soluble spore proteins (SASP)**. These proteins are specifically produced during the sporulation process, and they bind to bacterial DNA, compacting it. Because of this, DNA becomes more resistant to heat, desiccation, radiation. ... On the other hand, they also become a source of nutrients and energy, in the final stages of the germination process.

Inclusion bodies

Inclusion bodies are structures frequent in bacteria. They are granules of organic or inorganic material, which are usually surrounded by a single-layer protein membrane which isolates the inclusion body from the rest of the cytosol, though they can also be found free in the cytoplasm. Inclusions can usually be seen directly under the microscope without special staining.

The function of **inclusion bodies** is mainly to store energy reserve elements such as lipids or polysaccharides to use them as an energy source in conditions of nutrient scarcity or for the biosynthesis of molecules. Nevertheless, there are some inclusion bodies that accumulate other kind of substances, with very specific functions.

Why has this method of storing energetic compounds been evolutionarily successful? Probably because storing these elements as insoluble compounds allows the bacteria to accumulate more chemical energy in less space, and with less osmotic stress than if they had to store it as soluble substances, which would inevitably contribute to increasing the already high intracellular osmotic pressure.

These bodies allow to store a great variety of substances that make up the different inclusion bodies that exist. The most important are:

- **Poly-beta-hydroxybutyrate granules:** They are surrounded by a membrane and their formation occurs under conditions of excess carbon and will be degraded as carbon or energy sources when conditions demand it.
- **Polysaccharide inclusions:** Formed mainly by glucans such as starch or glycogen. They are also produced under conditions of excess carbon, and are degraded as carbon or energy source.
- **Biopolymers:** They can be completely degraded by the bacteria that produce them and by other types of microorganisms.
- **Sulfur globules,** in which sulfur is fundamentally accumulated and in which, for example, chemolithotrophic organisms use for their oxidation.
- **Magnetosomes:** Allows bacteria to orient themselves in a magnetic field. They are intracellular particles of magnetite (Fe_3O_4). The bacteria that present these elements have a property called magnetotaxis that allows them to move along the magnetic lines of the earth. They are more frequent in microorganisms that live under water.
- **Gas vesicles:** They are typical of planktonic microorganisms that live in the water columns of oceans and lakes. Thanks to these structures they can float. They are typical of cyanobacteria.

In Enterobacteria, the main element stored is glycogen and constitutes 40% of their weight. Mycobacteria have polyphosphate granules and some *Pseudomonas* accumulate carbon.

Introduction

Pathogenesis could be defined as a multi-factorial process which depends on several circumstances such as the nature or virulence of the species of microorganism, the number of these microorganisms in the initial exposure and the immune status of the host. Pathogenesis refers both to the mechanism of infection and to the mechanism by which disease develops. On the other hand, pathogenicity is the capacity to initiate any disease. It requires some characteristics such as the transmissibility to a host, infectivity in this new host and virulence or the capacity of the pathogen to cause disease. The capacity of a bacterium to cause disease reflects its relative pathogenicity; thus, the bacteria can be included in three groups according to its pathogenicity: primary pathogen, when a bacterium is isolated from a patient and is considered to be the probable agent of this infection in previously healthy individuals with intact immunological defenses. Opportunistic microorganisms are those isolated from patients whose host defense mechanisms have been impaired or compromised. Finally, other bacteria are considered to be non-pathogens due to the fact that they rarely or never cause human infection.

Another aspect of the bacterial infections is the bacterial persistence phenomenon because many bacteria can infect and persist inside their hosts for long periods of time. This fact can be due to immunosuppression of the host, immune evasion by the pathogen and/or ineffective killing by antimicrobials.

The purpose of this article is to provide an overview of the main mechanisms of pathogenicity, to describe the main virulence factors and their interactions with host defense mechanisms and their role in the pathogenesis of infections. In addition, description of the phenomenon of persistent bacterial infections and the presence of persister cells has been also developed.

Pathogenesis of bacterial infections

Pathogenesis refers both to the mechanism of infection and to the mechanism by which disease develops (Finlay and Falkow, 1989). It is well known that the pathogenic mechanisms of several infections are poorly understood but, basically, bacteria may cause disease by two mechanisms: direct damage of host cells by virulence factors, and indirectly by stimulating a great host inflammatory/immune response. There are some steps involved in the bacterial pathogenesis: transmission into the body by several routes, adhesion which is necessary to avoid innate host defense mechanisms, invasion or penetration in host cells and tissues, survival in the host, and tissue injury.

Host susceptibility

Susceptibility to bacterial infection is related with the immunologic and physiologic condition of the patient and with the virulence of the bacteria. When the microorganism has invaded the host, the first line defense barrier is a “nonspecific” mechanism which includes polymorphonuclear neutrophils and macrophages (Eisenstein et al., 1983) and the skin which contains a great variety of microorganisms in an enormous quantity. The normal microbiota of the skin and mucosal surfaces also protect the host against colonization by bacterial pathogens. Most bacteria present in this location and in the environment are relatively benign to persons with normal immune system. However, in immunosuppressed individuals like those with VIH infection or receiving chemotherapy, opportunistic microbial pathogens may cause severe infections. In addition, mucous membranes of the body (e.g., urogenital, gastrointestinal and respiratory systems) are locations through which microorganisms can entry to the body. In these locations, the presence of lysozyme, lactoferrin and lactoperoxidase can eliminate the bacteria or inhibit their growth.

After this, a specific immunity such as the antibody response to the bacteria is established in several weeks. People develop local specific antibodies for these bacteria. Antibodies cause lysis of the organisms and/or their opsonization by phagocytes and they are quickly killed. After phagocytosis, the bacterial microorganisms usually are killed. When an inflammatory process occurs, phagocytic cells, along with lymphocytes, play an important role in innate immunity to bacterial infections.

The mucous membranes also contain immunoglobulins, especially IgA, produced by plasmatic cells present in the submucosal tissue. In healthy persons, a bacterium present in the normal microbiota that may penetrate into the body is eliminated in most cases by the host's humoral and cellular mechanisms. On the other hand, persons with an altered immune system could be infected by these less virulent microorganisms causing recurrent infections. Moreover, in several circumstances such as the elderly or the infants, a decrease of the mechanisms of defense could be observed, being especially susceptible to some pathogens. Other patients have several genetic deficiencies of the complement system or cellular defenses or may develop a decrease of some mechanisms of defense as a consequence of various predisposing diseases like cancer, organ transplantation or chemotherapy.

Host defenses may be disrupted by other several circumstances or diseases such as cystic fibrosis, urinary tract obstructions, medical procedures or devices' implantation.

On the other hand, intracellular parasites are primarily killed by cell mediated immunity. Continuously generated antigens released from persisting microbes will elicit humoral antibodies and cell mediated immunity which will kill these bacteria.

Pathogenic mechanisms

Bacterial infectivity

Virulence factors are factors that are produced by some microorganisms and may cause disease in the host (e.g., toxins, surface receptors, ...). Many virulence factors are produced only by specific virulent strains of a bacterium (e.g., enterotoxins for some *E. coli* strains). The clinical course of a disease usually depends on the interaction of virulence factors and the response of the host. When the balance between virulence factors and host response is favorable to the first one, the infection begins.

Host-mediated pathogenesis

In some infections such as Gram-negative bacterial sepsis, tuberculosis and leprosy, the pathogenesis of these infections cannot be taken into account apart from the host immune response; in these cases, the tissue damage may be produced by the host response to the infection rather than by specific virulence factors of the bacteria. It is to highlight that the tissue damage in these circumstance is caused by several toxic factors produced by polymorphonuclear neutrophils, lymphocytes and macrophages which infiltrate the site of infection. When this cellular reaction occurs, the host response can be of great severity and intense and may cause proliferation of the bacteria and destruction of host tissue.

Intracellular growth

The capacity of bacteria to survive and multiply within host cells is an important factor of the pathogenesis to cause infection. The majority of bacteria do not enter within the cells and they prefer to proliferate in the extracellular matrix; some of them are able to attach to the epithelial surfaces secreting toxic substances or toxins. In most cases, bacteria present within cells or in the extracellular environment are eliminated from humoral antibodies or by a cellular immune response. However, other pathogenic bacteria can proliferate inside the cells due to some protection mechanisms. Some bacteria are able to survive intracellularly by releasing phospholipases which eliminate the phagocytic vesicle surrounding them (e.g., *Rickettsia rickettsii*). On the other hand, *Legionella pneumophila* may grow within the macrophages blocking the lysosomal fusion by unknown mechanisms. Other bacteria are able to grow in low-pH environment within the lysosomal granules such as *Coxiella burnetii*. In addition, some bacteria like *Salmonella* and *Mycobacterium* species are very resistant to the action of phagocytic cells.

Molecular and genetic basis for virulence

Virulence factors in bacteria may be encoded on both chromosomal and bacteriophage DNA, plasmids or transposons. Other virulence factors are acquired by bacteria after infection by a bacteriophage which integrates its genome into the bacterial chromosome. Other virulence factors are encoded on the bacterial chromosome (e.g., cholera toxin).

Specific virulence factors

Virulence corresponds to the pathogenicity of a microorganism. This characteristic is closely related to the ability of the pathogen to cause disease despite host resistance mechanisms. Virulence factors can be divided into two categories: those that cause damage to the host (e.g., toxins), and those that produce colonization and survival of infecting bacteria.

Bacterial toxins

There are two types of toxins: exotoxins and endotoxins (Berry, 1977). Exotoxins are protein molecules liberated from viable bacteria. Most of them are heat labile and are produced by some members of both Gram-positive and Gram-negative genera. They are excellent antigens that elicit protective antitoxic antibodies called antitoxins. The exact functions of these exotoxins for the bacteria are usually unknown and the site of action of most exotoxins is often localized in particular cell types or cell receptors. Exotoxins can be produced in several different ways: ingestion of preformed toxin (e.g., botulism), colonization of wound or surface followed by toxin production (e.g., diphtheria, cholera), and production by bacteria in tissues (e.g., *Clostridium perfringens*).

Based on their biologic effect on host cells, exotoxins may be classified into some categories such as neurotoxins, enterotoxins and cytotoxins. Cytotoxins constitute a heterogeneous group with a wide spectrum of toxic manifestations (e.g., diphtheria toxin produced by *Corynebacterium diphtheriae*). An example of neurotoxin may be those produced by *Clostridium* spp. (e.g., botulinum toxin produced by *Clostridium botulinum*). On the other hand, enterotoxins can stimulate hypersecretion of water and electrolytes from the intestinal epithelium that cause watery diarrhea (e.g., shiga-enterotoxin produced by *Shigella* spp., shiga-like enterotoxin produced by *E. coli*, cholera toxin...).

Other classification of exotoxins includes:

- (a) A-B toxins: these toxins act intracellularly, and they are composed of two components (A and B portions). The B portion binds to a specific host cell receptor and the A portion passes into the cells and has biological activity against a specific target.
- (b) Membrane damaging toxins: these toxins cause damage digesting enzymatically the components of membranes which leads to osmotic lysis and cell death. Some examples of these toxins are the enzymes that hydrolyze phospholipids (e.g., phospholipase, sphingomyelinase), toxins that disrupt by membrane solubilization (e.g., delta toxin of *S. aureus*) and pore forming toxins that insert in the membrane and form a hydrophilic pore.
- (c) Superantigens: they are toxins that bind directly to major histocompatibility complex II (MHC II) on macrophages and form a crosslink with T cell receptors. As a consequence of this, increased amounts of IL-2 are produced and further stimulation of other cytokines lead to shock production (e.g., staphylococcal toxic-shock syndrome).
- (d) Extracellular enzymes: they may cause severe tissue damage aiding in dissemination (e.g., coagulase, hyaluronidase and protease, collagenase and DNase).

The second group of toxins is the endotoxins which are toxic components of the bacterial cell envelope. Endotoxins are promoters of inflammation; the most potent endotoxin is the lipopolysaccharide (LPS) produced by Gram-negative bacteria. In addition, in Gram-positive bacteria peptidoglycan and teichoic acid are also endotoxins. The toxic effects of endotoxins include leukopenia followed by leukocytosis, pyrogenicity, complement activation, hypotension, induction of prostaglandin synthesis, hypothermia and mitogenicity. LPS binds CD14 and this complex binds Toll-like receptor 4 (TLR4) on macrophages and monocytes. On the other hand, TLR1 binds peptidoglycan and TLR2 teichoic acids. Macrophages and monocytes release cytokines inducing prostaglandin and leukotriene release. Thus, the complement and coagulation cascades are immediately activated. At the end of these events, sepsis and lethal shock may be produced with multiple organ system failure.

Factors involved in bacterial invasion of tissues

In this case, the host damage is caused by direct disruption of function or an increased immune response that affects tissue function. The invasive bacteria could be classified as obligate intracellular microorganisms (e.g., rickettsia, chlamydia), facultative intracellular bacteria (e.g., *Mycobacterium*) and extracellular pathogens. Overall, there are some steps in bacterial invasion:

1. Motility that uses several elements such as flagella, corkscrew, gliding motility or chemotaxis using a gradient.
2. To cause infection, many bacteria must first adhere to a mucosal surface and multiply. Bacteria have developed some attachment mechanisms by using two strategies: fimbriae (*pili*) and monomeric protein adhesins mediated by cell surface proteins.
3. Invasion of cells (in intracellular microorganisms): the specific bacterial surface factors that mediate invasion are unknown in the majority of cases, but there are two main mechanisms for invasion: bacteria can present ligands on their surface allowing to bind to host cells and initiate the entry process (zippering), and bacteria can inject effectors into host cells to regulate phagocytosis (triggering).
4. Manipulation of host cell functions: pathogens can alter some functions of host cells by injecting effector proteins directly into the host cell cytoplasm.

Survival in the host

Some microorganisms are able to resist the cytotoxic action of plasma and other body fluids by antibodies, complement or lysozyme. A major survival mechanism is the derision of phagocytosis by extracellular pathogens. With regard of this, the presence of capsule or secretion of protein A and/or protein M may have this function.

Protein A is a surface component of *S. aureus* binding to the Fc portion of immunoglobulins. Bacteria can activate the classical complement cascade which results in the attachment of fragments of C3. After this, phagocytosis can occur, but in the presence of protein A, interaction of bacteria with C3 receptors will be inhibited.

On the other hand, peptidoglycan such as LPS, can activate the alternate complement cascade. The M protein of the group A streptococci binds fibrinogen which blocks complement binding; thus, streptococci are non phagocytosed.

Finally, intracellular pathogens can survive within phage lysosomes or within phagosomes.

Bacterial persistence

Several bacterial infections are capable to persist in the host for long periods of time, even if antimicrobial treatment has been applied. Persisters were firstly described after the discovery of antibiotics by Joseph Bigger in 1944, when a culture of *Staphylococcus aureus* was not sterilized with high doses of penicillin (Bigger, 1944; Hobby et al., 1942). Several factors in both the host and the bacteria can contribute for the start-up and maintenance of persistent infections, including antimicrobial resistance and immunosuppression factors. Another important fact is the presence of persister cells that have been well demonstrated in *Escherichia coli*, *Pseudomonas aeruginosa*, *Mycobacterium tuberculosis*, *Salmonella enterica* subsp. *enterica* serovar Typhimurium and *Staphylococcus aureus* (Helaine and Kugelberg, 2014; Harms et al., 2016; Michiels et al., 2017). Persisters may cause antimicrobial treatment failure and can lead to the emergence of antibiotic resistance (Cohen et al., 2013; Levin-Reisman et al., 2017). Moreover, a decrease in metabolic activity has been demonstrated in the persister phenotype (Amato et al., 2014). These persisters could contribute to treatment failure of bacterial infections and to the evolution of genetic resistance. The effect of persistence could be applied for causing resistance to the majority of antibiotics.

Persister cell formation

It is well known that several circumstances increase the possibility of formation of persister cells such as nutrient limitation, extreme pH and DNA damage (Helaine et al., 2014; Maissoneuve et al., 2013; Dörr et al., 2010). The presence of biofilms that could be inhabited by bacteria can be also be associated with the formation of persisters by the fact of the presence of some or all of the cellular stresses factors above mentioned. Inside the biofilms, not all bacterial population form persisters due to the fact of the limitation of nutrients. The presence of macrophages can also induce the presence of persisters restricting nutrient availability and decreasing the pH.

On the other hand, phenotypic resistance permits a subpopulation of bacteria to keep growing in the presence of an antimicrobial.

Asymptomatic persistent infections may be caused by latent growth-arrested bacteria (e.g., tuberculosis, typhoid fever, urinary tract infections by *E. coli*, ...). On the other hand, symptomatic persistent infections have clinical manifestations over a long period of time usually despite antimicrobial therapy (Grant and Hung, 2013). Repetitive use of drugs for infections may also increase the selection of antibiotic-resistant strains and decrease of the normal microbiota (Jernberg et al., 2010). They often may be associated to the use of indwelling medical devices or to appear in patients with suppression of immunity (e.g., HIV infection, cancer, chemotherapy, ...).

The bacteria that cause persistent infections usually have never been cleared from the host during antimicrobial treatment.

The survival of persister cells is often explained by their transition to a dormant state characterized by a reduction of growth rate and metabolism. It has been proposed that bacterial communities generate a diverse quantity of dormant cells, but the nonreplicating state is not sufficient for survival because bacteriostatic conditions do not necessarily induce antimicrobial tolerance. In addition, persister formation involves specific qualitative changes of bacterial physiology to permit survival and resuscitation. Some studies have demonstrated that the signaling that controls bacterial persistence and the mechanisms related to persister formation are genetically encoded (Lewis, 2010). Another hypothesis explains the presence of persisters as nongrowing cells arising from errors and glitches (Levin et al., 2014).

Causes of persistent infections

Absence of clearance by the host

If not antimicrobial treatment has been applied, a persistent infection may be due to the failure of the host immune system to eliminate the pathogen as a consequence of absence of detection of the microorganism by the immune system. Some bacteria have developed mechanisms or strategies to avoid detection by the host; for example a variation of the expression of surface antigens in *Borrelia* species (Norris, 2006). Another mechanism is the possibility of the modulation of host immune response resulting in an ineffective clearance of the pathogen. In this case *L. monocytogenes* and *M. tuberculosis* induce the production of interleukin-10 in macrophages to suppress the interferon- γ -response (Redpath et al., 2001). Other mechanisms include the inhibition of maturation of phagosomes (Scott et al., 2003) and the inhibition of MHC class II antigen presentation in dendritic cells (Bayer-Santos et al., 2016).

On the other hand, the formation of biofilms has also been proposed as a mechanism to the persistence of some infections (Costerton et al., 1999). Finally, the formation of granulomas such as in *M. tuberculosis* leads to the absence of macrophages interaction and persistence of infection.

Absence of clearance by antimicrobials

When antibiotic treatment is being applied and no cure of infection can be observed, treatment failure could be due to some factors such as poor pharmacokinetics of drugs, low patient compliance and/or acquired antibiotic resistance (Kardas, 2002; Gonçalves-Pereira and Pôvoa, 2011; Blair et al., 2015). If not antimicrobial resistance is detected, bacteria can survive due to antibiotic tolerance. Both mechanisms, antibiotic resistance and tolerance can either occur in a whole population of bacteria or in a subpopulation.

Persistent infections and persister cells

During treatment with antibiotics, there are some bacteria that cause infections which were never cleared from the host; in this sense, studies with *Salmonella typhimurium* isolates have demonstrated that in cases of recurrent fever in these patients, around 80% were caused by the same *genovar* as the first infection (Okoro et al., 2012).

Genetic mutations in bacteria may increase antibiotic tolerance by slowing growth (Fridman et al., 2014). In addition, mutations can also increase the probability of persister formation in a clonal population. These mutations were firstly demonstrated in *E. coli* (*hipA7* mutation) being called high-persistence (*hip*) mutations (Moyed and Bertrand, 1983). Regarding to the patients affected by cystic fibrosis, they are usually infected by strains of *P. aeruginosa* and these isolates are more likely to be *hip* mutants if obtained later in infection (Mulcahy et al., 2010).

On the other hand, it has been observed that periodic treatment of *Candida* species with antifungals is able to select for *hip* mutants (Lafleur et al., 2010).

An important fact is the link established between the presence of persisters and biofilm formation; thus, several studies have showed that the formation of biofilms is associated with persistent infections (Costerton et al., 1999; Grant and Hung, 2013). Some examples of formation of biofilms are *P. aeruginosa* in patients with cystic fibrosis and uropathogenic strains of *E. coli* on the bladder epithelium.

Clinical relevance of persisters

Many patients may suffer from bacterial infections and despite the antimicrobial treatment these infections can be often chronic and are never fully cleared because these bacteria can persist in different ways (e.g., biofilm formation). Some clinical examples are the infections due to *M. tuberculosis*, urinary tract infections caused by uropathogenic strains of *E. coli*, opportunistic infections of implanted devices typically caused by *Staphylococcus* spp. and *P. aeruginosa*.

In some animal models of bacterial infections with these microorganisms, a heterogeneous population of persisters has been observed. In vitro, bacterial persisters show increased tolerance to antibiotic treatment and then induce microorganism persister formation. The usual treatment of chronic infections is linked to increased persister levels of clinical isolates and rapid selection for mutants. In this sense, different stress signaling pathways commonly involved in persister formation are known to increase mutations.

Introduction

Staphylococci belong to the Micrococcaceae family, which also includes Micrococcus, Stomatococcus, and Planococcus. These bacteria are catalase-positive gram-positive cocci that divide into irregular clusters and form a “grape bunch”-like clustering when viewed under the microscope. The genus *Staphylococcus* comprises microorganisms that are present in the mucosa and on the skin of humans and other mammals and birds, including a total of 51 species, of which 17 can be isolated from humans and cause a wide spectrum of systemic diseases that can be life-threatening (Tong et al., 2015). From a microbiological point of view, considering the ability to produce coagulase and the clinical picture, they can be divided into two groups:

- Coagulase positive staphylococci: *Staphylococcus aureus* is the most important; *S. argenteus*, *S. schweitzeri*, *S. intermedius*, *Staphylococcus pseudintermedius* and *Solanum coagulans* (previously *Staphylococcus schleiferi* ssp. *coagulans*).
- Coagulase negative staphylococci (CoNS): *Staphylococcus epidermidis* is the most prevalent; *Staphylococcus capitis*, *Staphylococcus cohnii*, *Staphylococcus haemolyticus*, *Staphylococcus hominis*, *Staphylococcus hyicus*, *Staphylococcus lugdunensis*, *Staphylococcus pettenkoferi*, *S. saccharolyticus*, *Staphylococcus saprophyticus*, *S. schleiferi*, *Staphylococcus sciuri*, *S. simulans*, *Staphylococcus warneri* and *Staphylococcus xylosus*.

Species most frequently associated with human disease are *S. aureus* (the most virulent and best-known member of the genus), *S. epidermidis*, *S. haemolyticus*, *S. lugdunensis*, and *S. saprophyticus*. Staphylococcal infections are one of the most prevalent, both in the community and in the hospital, according to the latest EPINE (Prevalence Study of Nosocomial Infection in Spain). *Staphylococci* are among the first causative agents of skin and soft tissue infections (IPPB), osteoarticular infections (IOA), bacteremia and endocarditis (Chalmers and Wylam, 2020). About 20% of the population is permanently colonized by *S. aureus*. The main reservoir for *S. aureus* is the nostrils of the carriers. Spread occurs from person to person through direct contact or exposure to contaminated fomites. The infection generally begins in areas with previous alterations of the mucocutaneous barrier. Colonization increases the risk of infection (Sakr et al., 2019).

It can act through toxins (alpha-hemolysin, Pantone-Valentine leucocidin [LPVL]) or superantigens (TSST-1, enterotoxins), or by invasion of any organ or tissue and cause suppuration, tissue necrosis, vascular thrombosis and bacteremia (McGuire et al., 2020). It is the microorganism with the greatest capacity to cause hematogenous metastasis. It can also form biofilms and lead to persistent and chronic infections (Oliveira et al., 2018).

Based on the susceptibility to oxacillin/methicillin, *S. aureus* is divided into two groups: methicillin-susceptible *S. aureus* (MSSA) and methicillin-resistant *S. aureus* (MRSA). MRSA causes resistance to almost all beta-lactam drugs except ceftaroline and ceftolozime (Chalmers and Wylam, 2020). The importance of MRSA has been made evident not only by the implications for a worse prognosis, but also by the increased demand for healthcare resources. Patients infected with MRSA require a greater number of diagnostic and antimicrobial tests and are associated with prolonged hospital stays and higher mortality (Morosini et al., 2012). For this reason, programs have been established to detect colonized individuals trying to reduce the risk of acquiring a MRSA infection (European Centre for Disease Prevention and Control, 2020a,b,c).

Epidemiology

According to the prevalence study recently published by the European Center for Diseases Control and Prevention (ECDC), *Escherichia coli* (44.2%) is the most important pathogen in nosocomial infection, the second being *S. aureus* (20.6%). Thirty countries in the European Union (EU) or the European Economic Area (EEA) reported 2019 data to the European Antimicrobial Resistance Surveillance Network (EARS-Net). (European Centre for Disease Prevention and Control, 2020a,b,c). For *S. aureus*, there is a decrease in the percentage of methicillin-resistant isolates (i.e., MRSA) reported compared to previous years. However, MRSA remains an important pathogen in the EU/EEA, with levels still high in several countries, and combined resistance to another group of antimicrobials was common (European Centre for Disease Prevention and Control, 2020a,b,c). In general, northern European countries reported lower percentages of resistance and southern and eastern European countries reported higher percentages (World Health Organization, 2015).

EU/EEA population-weighted mean percentage of MRSA was 15.5% in 2019. This denotes a significantly downward trend for the period 2015–2019. Among MRSAs, combined resistance to another group of antimicrobials was common. The most common resistance combination was MRSA and fluoroquinolone resistance. Many countries have developed and implemented national recommendations and guidance documents on preventing the spread of MRSA, focusing both on improving infection prevention and control and the prudent use of antimicrobials (European Centre for Disease Prevention and Control, 2018). Despite this positive development, MRSA remains a major pathogen in Europe. *S. aureus* is one of the most common causes of bloodstream infections and has a high burden in terms of morbidity and mortality. Hospital clones (HA-MRSA) were the first to emerge and responsible for the large increase in MRSA in hospitals during the 1980s and 1990s. In some Asian countries, the dispersal of HA-MRSA clones in the community has been observed, behaving like community clones (CA-MRSA) (Cantón and Ruiz-Garbajosa, 2013).

For this reason, universal screening programs have been established for patients admitted to hospitals to detect colonized individuals, trying to reduce the risk of acquiring a MRSA infection. This action has allowed a drastic decrease in MRSA infection (Cantón and Ruiz-Garbajosa, 2013).

Microbiology

These bacteria are catalase-positive gram-positive cocci that are characterized by not forming spores, they are spherical in shape. Most staphylococci are 1.5 µm tall, immobile, and capable of growing under a variety of facultative aerobic and anaerobic conditions in the presence of high salt concentrations (e.g., 10% sodium chloride) and at temperatures 18–40 °C, except for *S. saccharolyticus* and *S. aureus* ssp. *anaerobius*, which are strictly anaerobic. *S. aureus* produces acute infections, associated or not with toxins, of any location, although the most common are skin and soft tissue (IPPB), osteoarticular (IOA), bacteremia, endocarditis and pneumonia. In contrast, CoNS infections are more long-standing and are mainly related to the presence of foreign bodies, with bacteremia associated with vascular catheters being very common (Murray et al., 2021).

Coagulase-negative staphylococci are normal commensals on the skin and mucosa of various mammalian hosts. *S. epidermidis* is the most prevalent species on human skin. Given the variable characteristics of human skin, including its moisture, nutrients, pH range, and temperature, *S. epidermidis* can adapt to different environmental conditions. Some species of coagulase-negative staphylococci are well adapted for survival in specialized niches, such as *S. capitis* (in the human scalp), *Staphylococcus auricularis* (in the human external auditory canal), and *S. saprophyticus* (in the human scalp, digestive and genitourinary tracts of the human population) (Becker et al., 2014).

Mechanisms of pathogenicity

Virulence factors include structural components that facilitate adherence to host tissues and prevent phagocytosis, and a variety of toxins and hydrolytic enzymes. Among the structural components of *Staphylococcus* are the following:

- Capsule: it is the outermost layer of the staphylococcal cell wall, 11 capsular serotypes of *S. aureus* have been identified:
 - Serotypes 1 and 2 are associated with thick capsules and colonies with a mucoid appearance, but they rarely cause disease in people.

- o Serotypes 5 and 8 are responsible for the majority of human infections. The capsule protects bacteria by inhibiting phagocytosis of these microorganisms by polymorphonuclear leukocytes (PMN).
- Silt or biofilm layer: most *staphylococci* have a loose water-soluble layer made up of monosaccharides, proteins, and small peptides. Facilitates adherence to tissues and foreign bodies, such as catheters, grafts, valve and joint prostheses.
- Peptidoglycan: it is formed by layers of glucan chains built with 10 or 12 alternating subunits of *N*-acetylmuramic acid and *N*-acetylglucosamine. Gram-positive microorganisms are composed of numerous interlocking layers, which confer greater rigidity to the cell wall. The enzymes that catalyze the construction of the peptidoglycan coat are called penicillin-binding proteins because they are the targets for penicillins and other β -lactam antibiotics. Bacterial resistance to methicillin and related penicillins is mediated by the acquisition of a gene (*mecA*) that encodes a new penicillin-binding protein, PBP2a. The *mecA* gene is located on the staphylococcal *mec* cassette (SCCmec) chromosome and six gene sequences are described in this cassette (types I-VI). This information is important because MRSA strains, previously limited to hospital infections, now appear in the community and are responsible for the majority of staph infections. These strains usually have type IV SCCmec, these strains have moved from the community to the hospital (Kwiecinski and Horswill, 2020).
- Teichoic acids: they are specific phosphate polymers bound to *N*-acetylmuramic acid residues of the peptidoglycan layer or through a lipophilic bond to the cytoplasmic membrane. They stimulate a specific humoral response.
- Surface adhesion proteins: they are covalently bound to the peptidoglycan of the cell wall in staphylococci and have been designated as MSCRAMM (Microbial Surface Components Recognizing Adhesive Matrix Molecules) proteins, components of the microbial surface that recognize matrix molecules adhesive. The best characterized MSCRAMM proteins are staphylococcal protein A, fibrin-binding proteins A and B, and aggregation factor proteins A and B. The aggregation factor proteins (also called coagulase) bind to fibrinogen and convert it into fibrin; this constitutes the identification test of *S. aureus* (Balasubramanian et al., 2017).

Staphylococcal infections depend on the ability of bacteria to evade phagocytosis, produce adhesion proteins of the bacteria to host tissues, and produce tissue destruction through the manufacture of specific toxins and hydrolytic enzymes. In the expression of virulence factors, the most important is the AGR (accessory gene regulator). This quorum sensing control system allows the expression of adhesion proteins and promotes tissue colonization when the density of bacteria is low and of hydrolytic enzymes and toxins when the density is high.

Among the components of staphylococcal toxins are the following:

- Five cytolytic toxins (hemolysins) that damage the membrane (alpha, beta, delta, gamma, and Panton-Valentine [P-V] leucocidin).
- Two exfoliative toxins (A and B).
- 18 Enterotoxins (A to R).
- Toxin-1 from toxic shock syndrome (TSST-1).

Cytotoxins can cause lysis of neutrophils, resulting in the release of lysosomal enzymes that subsequently damage surrounding tissues. A cytotoxin, P-V leucocidin, has been linked to severe lung and skin infections. Exfoliative toxin A, enterotoxins, and TSST-1 belong to a class of polypeptides known as superantigens (Murray et al., 2021).

Cytotoxins

- Alpha toxin is a 33,000 D polypeptide produced by most *S. aureus* strains that cause disease in humans. The toxin disrupts the smooth muscle of the blood vessels and is toxic to many cells. It is a mediator of tissue damage in staphylococcal disease.
- Beta toxin is a 35,000 D thermolabile protein produced by most of the *S. aureus* strains that cause disease in humans. Catalyzes the hydrolysis of membrane phospholipids in susceptible cells. It is responsible for the differences in susceptibility of different species to the toxin.
- Delta toxin is a 3000 D polypeptide produced by almost all *S. aureus* strains and most staphylococcal species. It has cytolytic activity. It alters cell membranes through a detergent-like action.
- Gamma toxin (manufactured by most strains of *S. aureus*) and Leucocidin PV are toxins made up of two components that consist of two polypeptide chains: the S component (slow eluting proteins) and the F component (proteins of rapid elution). Proteins S (and two proteins F) have been identified. Bacteria that produce both toxins code to produce six different toxins. These six toxins can lyse neutrophils and the most intense lytic activity. It is encoded by mobile phage. PV leucocidin toxin is leucotoxic, but it lacks hemolytic activity.
- Leucocidin toxin PV has generated great interest because, although it is found in less than 5% of all hospital MRSA strains, it is identified in virtually all MRSA strains associated with community infections (soft tissue infection and pneumonia in young people) (Oliveira et al., 2018).

Exfoliative toxins

Scalded skin syndrome (SPEE) is characterized by exfoliative dermatitis. It is seen in young children and is rarely described in older children or adults.

Two different forms of exfoliative toxin have been identified (ETA and ETB), and both can cause disease. ETA is heat stable and the gene associates with a phage, while ETB is heat labile and is located on a plasmid. The toxins are serine proteases that break down desmoglein-1, so staphylococci are not present in the affected epidermis layer. After exposure of the epidermis to the toxin, protective neutralizing antibodies develop, leading to resolution of the toxic process.

Enterotoxins

18 staphylococcal enterotoxins (A to R) have been identified:

- Enterotoxin A is the one most frequently associated with food poisoning.
- Enterotoxins C and D are found in contaminated dairy products.
- Enterotoxin B produces pseudomembranous colitis.

They are perfectly designed to cause foodborne diseases, as they are stable even when heated to 100 °C for 30 min and resist hydrolysis by gastric and jejunal enzymes. Therefore, when a food product is contaminated with enterotoxin-producing staphylococci and toxins are produced, neither mild reheating of the food nor exposure to gastric acids will be protective. These toxins are produced in 30–50% of *S. aureus* strains (Oliveira et al., 2018).

Toxin-1 toxic shock syndrome toxin-1

It is estimated that 90% of the strains of *S. aureus* that cause menstrual toxic shock syndrome (TSS) and half of the strains that cause other forms of TSS produce TSST-1. Enterotoxin B and enterotoxin C originate half of the TSS cases not associated with menstruation. TSST-1 is a superantigen that stimulates the release of cytokines and causes extravasation of endothelial cells, it has a cytotoxic effect on cells. The ability of TSST-1 to cross mucosal barriers causes the systemic effects of SST. Death in patients with TSS occurs as a consequence of hypovolemic shock that causes multiple organ failure.

Staphylococcal enzymes

- Coagulase: *S. aureus* strains have two forms of coagulase: bound and free.
 - o The bound coagulase/aggregation factor/clumping factor binds to the surface of the staphylococcal cell wall directly converting fibrinogen to insoluble fibrin to form staphylococcal aggregation (*S. aureus*, *S. lugdunensis*, *S. schleiferi* ssp. *schleiferi* and *S. sciuri*).
 - o Free coagulase achieves the same result by reacting with a globulin-like plasma factor (coagulase-reactive factor) to produce a thrombin-like enzyme. This factor catalyzes the conversion of fibrinogen to insoluble fibrin (*S. aureus*, *S. intermedius*, *S. schleiferi* sub *coagulans*, and *S. lutrae*).
 - o The role of coagulase can cause the formation of a fibrin layer around the staphylococcal abscess, the infection is localized, and the microorganisms are protected from phagocytosis (Tam and Torres, 2019).
- Hyaluronidase: hydrolyzes hyaluronic acids, present in the acellular matrix of connective tissue. Staphylococci hydrolyze host tissue components and aid in the spread of bacteria.
- Fibrinolysin: can dissolve fibrin clots.
- Lipases: All *S. aureus* strains and more than 30% of all coagulase negative *Staphylococcus* strains produce several different types of lipases, which hydrolyze lipids and ensure survival of staphylococci.
- Nuclease: *S. aureus* also produces a thermostable nuclease, which can hydrolyze viscous DNA.

S. aureus is one of the microorganisms with the most pathogenic mechanisms for developing infections. It can act through toxins (alpha-hemolysin, Panton-Valentine leucocidin [LPVL]) or superantigens (TSST-1, enterotoxins), or by invasion of any organ or tissue and cause suppuration, tissue necrosis, vascular thrombosis and bacteremia (Sadeghi et al., 2017). It is the microorganism with the greatest capacity to cause hematogenous metastasis. It can also survive in the cell cytoplasm, form biofilms and lead to persistent and chronic infections or remain quiescent and reactivate later. Likewise, in the cell cytoplasm it can undergo phenotypic changes consisting of the formation of so-called Small Colony Variants with intracellular persistence capacity, which is one of the mechanisms by which this microorganism can cause chronic or recurrent infection. They are slow-growing, punctate colonies, not pigmented, not beta-hemolysis. They usually occur in cystic fibrosis, osteoarticular devices and infections. Need for prolonged treatments with rifampicin associations. But the most common cause of chronic staphylococcal infection that is resistant to antibiotic treatment or recurrent is the formation of biofilms in vascular catheters, bone sequestration, pacemakers or any type of endovascular foreign material (Melter and Radojevič, 2010). The permanence of venous catheters with *S. aureus* infection is often a cause of persistent or recurrent bacteremia and distant septic complications.

Biofilm formation is also the main pathogenetic mechanism of CoNS, with the production of toxins and extracellular enzymes occupying a secondary place (Lister and Horswill, 2014).

S. saprophyticus causes urinary tract infections due to certain proteins that allow it to bind to the urothelium and a urease that contributes to cytopathic action and tissue invasion.

S. lugdunensis behaves like *S. aureus*, producing acute and severe infections. Its virulence has been related to multiple mechanisms, among which the following stand out:

- Production of adherent surface proteins that bind to tissues and foreign bodies.
- Formation of biofilms

- Resistance to lysozyme and elaboration of a delta-like hemolysin similar to the delta-hemolysin of *S. aureus*.
- The presence of sequences related to the *agr* (accessory gene regulator), a quorum-sensing system, which acts as a global regulator of virulence factors.

Clinical manifestations

Suspicion of a staphylococcal infection should be raised in certain situations. While *S. aureus* infections are acute and severe, those caused by CoNS are usually subacute and related to foreign bodies, with the exception of *S. saprophyticus*, which causes mild urinary tract infections in young women in late summer and *S. lugdunensis* with a behavior similar to that of *S. aureus*.

MRSA-C produces outbreaks with great dissemination capacity in groups of homosexuals, injecting drug users, residents of geriatric centers, athletes, soccer players, prisoners and the military, among others. These are mainly IPPB of varying severity and pneumonia with a tendency to necrosis (Tong et al., 2015).

Clinical manifestations of *Staphylococcus aureus*

- Scalded skin syndrome (SPE) due to exfoliative toxins A and B. Locally or generalized, blisters of clear fluid with positive Nikolsky's sign appear and self-limit in 4–7 days, probably the time needed to synthesize antitoxin immunoglobulins. It mainly affects infants producing a disseminated desquamation of the epithelium generating blisters devoid of microorganisms or leukocytes. Treatment focuses on hydric replacement. Antibiotic treatment is not indicated because the disease has been caused by a preformed toxin (Leung et al., 2018; Del Giudice, 2020).
- Food poisoning by enterotoxins due to ingesting contaminated food (processed meats, cream puffs, etc.) with the thermostable toxin, presents a rapid onset of intense vomiting, watery diarrhea and colic, resolving within 24 h.
- Toxic shock syndrome (TSS) caused by toxic shock toxin 1 or exotoxin B or C behaving like a superantigen. It can be given during menstruation or not related to it. In the first case, it has been associated with the use of high-absorption buffers, and in the second, the responsible *S. aureus* can colonize any location in the patient. Clinically, it is characterized by high fever, hypotension, generalized edema, hypoalbuminemia, and a morbilliform rash that peels off within a few days. The toxin is produced locally and blood cultures are typically negative. It presents high mortality in the absence of immediate antibiotic treatment and elimination of the focus of the infection (Silversides et al., 2010).
- Impetigo: localized superficial skin infection characterized by the presence of pus-filled vesicles on an erythematous base on the face and extremities, especially in young children.
- Folliculitis: pyogenic infection that affects the hair follicles (Del Giudice, 2020).
- Boils: large painful skin nodules filled with pus and necrotic tissue accumulated underneath.
- Anthrax: union of boils with extension towards the subcutaneous tissues and signs of systemic disease (fever, chills, bacteremia).
- Bacteremia and endocarditis: spread of bacteria into the blood from a source of infection, most are acquired in the hospital after surgery or after a contaminated intravascular catheter; endocarditis is characterized by damage to the endothelial lining of the heart, which can lead to peripheral septic embolization (*S. argenteus*, *S. intermedius*, *S. pseudintermedius* and *S. coagulans*) (Taquin et al., 2019).
- Pneumonia and empyema: consolidation and abscess formation in the lungs; it is observed in very young and elderly subjects, and in patients with underlying lung disease; A severe form of necrotizing pneumonia with septic shock and high mortality has been recognized. Empyema affects 10% of patients with pneumonia, purulent material is drained (*S. intermedius*, *S. pseudintermedius*) (Grau, 2017).
- Osteomyelitis: destruction of bones in the metaphyseal area of long bones after hematogenous bone spread or infection as a consequence of trauma or extension of an adjacent infection. It is characterized by bone pain and high fever.
- Septic arthritis: painful erythematous joint with accumulation of purulent material in the joint space, usually in the form of vertebral osteomyelitis, presenting low back pain with fever. It occurs in young children and adults who receive intra-articular injections or joints with mechanical abnormalities.

Clinical manifestations of coagulase negative staphylococci (CoNS)

Previously considered non-virulent contaminants, CoNS have been increasingly recognized as true pathogens, related to foreign bodies and prosthetic devices.

CoNS are the cause of approximately 30% of bacteremia cases. Immunosuppressed patients are at increased risk of bacteremia.

Since CoNS (especially *S. epidermidis*) occupy a prominent place in the commensal flora of human skin and mucosa, they often appear as contaminants in cultures.

Patients with clinical signs of sepsis and multiple positive cultures revealing bacterial growth in less than 24 h are more likely to experience true bacteremia.

When the blood in the catheter is positive 2 or more hours before the peripheral blood, this can be considered an indication that the catheter is the origin of the bacteremia (Murray et al., 2021).

- Wound infections: characterized by the presence of erythema and pus at the site of a traumatic or surgical wound; *S. aureus* and CoNS can cause foreign body-associated infections.
- Infections of the genitourinary tract: dysuria and pyuria in sexually active young women (*S. saprophyticus*), subjects with urinary catheters (other CoNS) or after inoculation of the genitourinary tract due to bacteremia (*S. aureus*).
- Catheter and shunt infections: chronic inflammatory response to bacteria lining a catheter or shunt (most often by CoNS).
- Prosthetic infections: chronic device infection characterized by localized pain and mechanical failure of the device (most often due to CoNS).
- Endocarditis is characterized by damage to the endothelial lining of the heart, *S. epidermidis* and *S. lugdunensis* can infect prosthetic valves more frequently.

Apart from *S. epidermidis*, there are other species of coagulase negative staphylococci that must be specifically exposed due to their pathogenic potential and other special characteristics.

Staphylococcus haemolyticus

It is the second or third most frequent species of CoNS implicated in infectious conditions. They are usually nosocomial bacteremia related to intravascular catheters, skin and soft tissue infections, urinary tract infections, meningitis, endocarditis, and device-associated infections. *S. haemolyticus* has been implicated in outbreaks in neonatal ICUs. The most notable feature of *S. haemolyticus* is that it is often resistant to multiple antibiotics, including glycopeptides (Becker et al., 2014).

Staphylococcus lugdunensis

It behaves clinically similar to *S. aureus* and has been shown to cause fulminant endocarditis of native and prosthetic valves, suppurative skin infections, bacteremia, eye, urinary tract, central nervous system, bone and joint infections, and peritonitis. *S. lugdunensis* has been reported to be more virulent because it can produce several virulence factors, as well as various enzymes such as DNase and lipase, as well as being resistant to lysozyme and can form biofilm.

Identification can be difficult. *S. lugdunensis* is easily confused with *S. aureus* when identification is based solely on the latex agglutination test. Fortunately, this organism is usually susceptible to most antistaphylococcal antibiotics because only about 25% of strains show beta-lactamase production and also because resistance to methicillin is rare. Infections caused by *S. lugdunensis* are treated similarly to those caused by *S. aureus*.

Staphylococcus schleiferi

S. schleiferi appears to be a significant cause of skin infections and otitis in companion animals. It produces very aggressive infections, presenting a small beta-hemolysis.

Staphylococcus saprophyticus

S. saprophyticus colonizes the rectum or urogenital tract of approximately 5–10% of women and is the second most common cause of uncomplicated urinary tract infections in young, sexually active women, after *E. coli*. They occur in late summer and fall, often appear after intercourse or menstruation, and can occur simultaneously with vaginal yeast infection.

90% of the patients with urinary tract infections due to *S. saprophyticus* present symptoms with dysuria, urgency and polyuria, and 80% present pyuria or hematuria.

It is resistant to novobiocin and is susceptible to other antibiotics, and urinary tract infections caused by *S. saprophyticus* are adequately treated with specific antibiotics (Becker et al., 2014).

Diagnosis

Diagnosis of staphylococcal infections is based on the data that make them suspect comorbidity, existence of entry points and clinical manifestations. Common comorbidity is mainly diabetes mellitus, chronic skin diseases, chronic kidney failure on dialysis, ADVP, previous flu, etc. The principal entry points are both skin lesions and devices such as vascular catheters, endotracheal tubes, implants, etc. Characteristic clinical presentation involves abscesses, septic metastases, bacteremia, endocarditis, joint and soft tissues infections.

According to previous studies, the recommended locations for sample collection are nasal swab and cutaneous exudate from the perineal area. The nasal swab is the most appropriate location, although it can be replaced by pharyngeal exudate. With greater susceptibility is the triple sample of nasal, pharyngeal and perirectal or perineal exudates. In patients with mechanical ventilation or tracheostomy, samples of respiratory secretions are also recommended. Other samples, depending on the clinic, are: exudate from ulcers or wounds in patients with broken skin, urine culture in patients with a urinary catheter, blood cultures, ocular and auricular exudates, sterile fluids (articular, pericardial, CSF, etc.) (Mandell et al., 2020).

These samples can be stored for less than or equal to 24 h, at room temperature or in a refrigerator between 2 °C and 8 °C. They do not require any type of preparation prior to inoculation in the culture media. For its culture, the swab is discharged in approximately one third of each plate, rotating it on itself and finally it is extended with a sterile loop in a qualitative way to obtain isolated colonies (Datta et al., 2011).

From a microbiological point of view, in any moderate or severe staphylococcal infection, blood cultures should be performed, samples of the possible primary or metastatic focus obtained, and a nasal swab. The latter is of particular interest when it is not possible to obtain samples from the source of sepsis, since it allows early identification of the state of colonization by *S. aureus* and to know its susceptibility to methicillin. If the patient has not received antibiotic treatment and the blood culture is extracted by venipuncture, a growth time of less than 14 h suggests the existence of an endovascular focus. If the initial blood cultures confirm the existence of staphylococcal bacteremia, they should be repeated every 3 days, as long as they remain positive. The susceptibility profile will allow a targeted treatment.

Microscopy

Staphylococci are gram-positive cocci that form clusters when grown on agar medium, but are generally seen in clinical specimens as single cells or small clusters of microorganisms. Swab or scrape samples from the base of the abscess show large numbers of organisms on Gram stain. The pus aspirate contains necrotic material with a relatively low number of organisms (Murray et al., 2021).

Culture

Clinical specimens should be inoculated onto enriched agar media supplemented with sheep's blood. The most widely used culture medium is blood agar, where the microorganism is subjected to definitive identification. *Staphylococci* grow rapidly on non-selective media, both aerobically and anaerobically, and large, smooth colonies can be seen within 24 h, gradually turning golden. Almost all strains of *S. aureus* and some strains of coagulase-negative staphylococci produce hemolysis on sheep blood agar (Harbarth et al., 2011).

S. aureus in a variety of special media:

- Champagne Medium or Mannitol-Salt Agar: It is a selective medium for staphylococci due to its high content of 5% sodium chloride (Han et al., 2007). Incorporates mannitol and phenol red, allows differences:
 - o Positive mannitol: forming yellow colonies (*S. aureus*, *S. simulans*, *S. sciuri*, *S. cohnii*, *S. capitis*, *S. xylosus*, *S. saprophyticus*, *S. haemolyticus*, *S. warneri*).
 - o Negative mannitol: forms white colonies (*S. epidermidis* and others).
- CHROMAgar *S. aureus*: selective chromogenic medium for *S. aureus* (Chihara et al., 2009).
- CHROMAgar MRSA: Chromogenic medium for the detection of methicillin resistant *S. aureus* (MRSA) (Malhotra-Kumar et al., 2010).
- Medium for the detection of DNase: It is a standard medium for the determination of deoxyribonuclease. Positive organisms will be surrounded by transparent areas of depolymerized DNA (*S. aureus*, *S. schleiferi*, *S. intermedius*, *S. hyicus*).

In the case of a positive gram-positive coconut, catalase, DNase, mannitol and coagulase with growth on MRSA agar (composed of Mueller-Hinton agar supplemented with 4% NaCl and 6 µg/mL oxacillin), the microorganism is identified as MRSA and it is performed antimicrobial susceptibility tests (Wendt et al., 2010; Glick et al., 2014).

Identification

Relatively simple biochemical tests (e.g., positive reactions for coagulase, protein A, thermostable nuclease, and mannitol fermentation) can be used to differentiate *S. aureus*. The identification of coagulase-negatives is more complex and requires the use of commercial identification systems or the detection of species-specific genes through nucleic acid sequencing (Murray et al., 2021).

Phenotypic or genotypic methods can be used to confirm methicillin resistance.

- Phenotypic
 - o Disc diffusion method: cefoxitin disc (30 µg) which is a potent inducer of PBP2a production, a transpeptidase with low affinity for beta-lactam antibiotics but which retains its function in cell wall synthesis, being responsible for resistance to methicillin.
 - o Automated or commercial systems such as Microscan, Vitek and Phoenix systems that use oxacillin and cefoxitin for the detection of MRSA (Sáinz-Rodríguez et al., 2019).
- Genotypic
 - o Confirmation of methicillin resistance in a culture dish can be performed by detecting the *mecA* gene (encoding PBP2a) by conventional or real-time polymerase chain reaction (PCR). It can also be done by latex agglutination to detect the presence of PBP2a. These confirmation methods require prior identification of the microorganism species (*S. aureus*) because resistance to methicillin in coagulase negative strains of staphylococci is also mediated by the *mecA* gene and its product, PBP2a (Arnold et al., 2016; Dupieux et al., 2016; Tasse et al., 2016).

- o PBP2a Immunochromatography: This is a qualitative chromatographic immunoassay for the rapid detection of penicillin binding protein 2a (PBP2a) in previously identified colonies, to help identify methicillin-resistant *S. aureus* (MRSA). It is based on nitrocellulose membrane technology where highly sensitive recombinant monoclonal antibodies (rFabs) and a control protein bind. Results are visually read after 15 min (Sáinz-Rodríguez et al., 2019).

The test can be performed from a direct sample of positive blood cultures with good results. Others are also obtained by performing the identification by MALDI TOF mass spectrometry (Bruker®) from microcolonies a few hours after subculturing the positive blood cultures and the detection of PBP 2a when it comes to *S. aureus*, producing results in a few hours. of great repercussion in the management of the patient (Delpont et al., 2016).

Molecular methods

Based on the performance of a PCR whose objective is to amplify a DNA fragment so that it is easier to identify the microorganism that causes a disease. In the case of MRSA, they detect DNA sequences related to resistance, specifically SCCmec, a mobile genetic element called the mec chromosomal cassette, which carries the mecA gene responsible for resistance (Rocchetti, 2018).

The need to obtain a rapid result in surveillance studies for MRSA has favored the development of molecular tests for its detection. These rapid methods mainly include real-time PCR amplification and allow results to be obtained within 2–6 h.

Currently, the methods based on the PCR reaction for the detection of the mec gene are considered of reference for the detection of MRSA. Detection of the mec gene allows differentiation from other strains of *S. aureus*, very rare, BORSA. MRSA strains with a negative mecA PCR result should be tested for the possible presence of the mecC gene (Paterson et al., 2014). Recently, commercial methods have been developed that include the detection of the mecC gene (Patel et al., 2015).

In hospital outbreak situations in which a rapid response is necessary to avoid the spread of this pathogen, it is of great relevance to have a technique capable of identifying these strains quickly and easily, generating great benefit in socio-economic terms and sanitary as it facilitates early isolations and effective treatments (Larsen et al., 2014).

Antibody detection

Many patients with long-standing *S. aureus* infections have antibodies to teichoic acids in the cell wall. However, this test is no longer performed in many hospitals because it is less sensitive than culture-based or nucleic acid-based tests.

Treatment

Depending on the susceptibility to oxacillin/methicillin, *S. aureus* is divided into two groups, those susceptible to it and those resistant (MRSA) since resistance to this compound causes resistance to almost all beta-lactam drugs, the main group of antibiotics used in its treatment (Rao et al., 2016).

This microorganism is usually susceptible to macrolides, clindamycin, fluoroquinolones, aminoglycosides, rifampicin, and cotrimoxazole, although strains resistant to each of these compounds may appear.

Clinical isolates of coagulase-negative staphylococci are usually more resistant to antibiotics and more than 50% of strains are resistant to oxacillin.

There are different ways to determine the antibiotic susceptibility of these microorganisms:

- Disc-plate system: it uses discs with an established concentration of each antibiotic and the inhibition zone produced by each antibiotic is determined.
- Epsilon test system: uses strips with a gradient of various concentrations of each antibiotic.
- Automated microdilution systems that are capable of determining the minimum inhibitory concentration (MIC) of each antibiotic. The cut-off points for a strain to be susceptible or resistant to an antibiotic depend on the antibiotic and are established by CLSI (Clinical Laboratory Standard Institute) or EUCAST (European Committee on Antimicrobial Susceptibility Testing) (Larrosa et al., 2020).

Fortunately, there are several new antibiotics that have been successfully marketed that possess adequate antibacterial activity against staphylococci, such as daptomycin, linezolid, and tigecycline. On the other hand, there are also several antibiotics activity against coagulase-negative staphylococci, such as dalbavancin, telavancin, oritavancin, iclaprim, ceftobiprole and ceftaroline. An important aspect of the treatment of most infections caused by CoNS is the ability of these infections to form biofilms on biomaterials (e.g., catheters, prostheses). However, combinations of antibiotics with rifampin appear to show promise in the treatment of biofilm-associated staphylococcal infections (Khan et al., 2018).

Staphylococcus aureus infections

Intravenous (IV) cloxacillin is the treatment of choice for moderate or severe SASM infections. It is recommended to administer it at intervals of no more than 4 h and continuous infusion is even preferable, in order to maintain the serum concentration, between consecutive doses, 4–5 times above the MIC. It is indicated in any type of infection with the following exceptions:

1. If there is biofilm formation on prosthetic material, or phenotypic variants of small colony.
2. Severe forms caused by strains that produce LPVT.
3. Localization in areas not easily accessible to beta-lactam administered by the systemic route, such as the eyeball and suppurative collections that for whatever reason cannot be drained immediately and completely.

Mild SASM infections can be treated orally with amoxicillin-clavulanate or cephalosporins whose minimum inhibitory concentration (MIC) against *S. aureus* is ≤ 4 mg/L (Rao et al., 2016).

Vancomycin is no longer the treatment of choice for methicillin-resistant staphylococcal infections (MRSA and most CoNS) due to:

- a) Its lower efficacy than isoxazole penicillins or cefazolin in the treatment of MSSA infection.
- b) The observation of failure rates above 30% in bacteremia, endocarditis, pneumonia and ATI.
- c) The worst prognosis seen in MRSA infections when the MIC₉₀ is > 1 mg/L. This last aspect has been related to the difficulty of complying with the PK/PD index that best predicts the efficacy of vancomycin (Fu et al., 2020).

Another option is to use vancomycin in continuous infusion that allows reaching the desired serum concentration earlier and maintaining it without fluctuations, although it has not improved the clinical response, it does seem to have a lower risk of toxicity. These facts have led to the consideration of the use of vancomycin for the treatment of MRSA infection (or MSSA infection in patients allergic to beta-lactams) when:

- a) The MIC against the causative strain is ≤ 1 mg/L or is unknown but the infection is mild or moderate.
- b) The infection does not occur with the formation of biofilms, nor is it located in areas of limited diffusion.
- c) Glomerular filtration rate is ≥ 40 mL/min and the patient does not receive other potentially nephrotoxic medication.
- d) The means are available to determine the serum concentration of vancomycin in the first 48 h of treatment and to know the result in the 24 h after taking the sample, in order to adjust the dose to the value of the desired trough concentration (Fu et al., 2020).

Linezolid is considered the antibiotic of choice for the treatment of pneumonia, meningitis and endophthalmitis caused by MRSA (or by SASM in patients with anaphylactic allergy to penicillin). It is also associated, associated or not with rifampicin, in the infection of prosthetic material by MRSA and is an alternative to the association of a fluoroquinolone with rifampicin for the oral treatment of MSSA infection. Linezolid is one of the antibiotics of choice in moderate or severe IPPB caused by MRSA (or SASM in patients with anaphylactic allergy to penicillin); and in monotherapy or association in any staphylococcal infection caused by a strain of *S. aureus* that produces enterotoxins or LPVT, regardless of the location of the infection and the susceptibility of the isolate to beta-lactams (Shariati et al., 2020).

Daptomycin is the treatment of choice in:

- a) Primary or catheter-associated bacteremia due to MRSA (or anaphylactic allergy to beta-lactam SASM).
- b) MRSA endocarditis (or MSSA in patients with anaphylactic allergy to beta-lactams) at a dose of 10 mg/kg/day, alone or in combination with other antimicrobials (fosfomycin and/or gentamicin—depending on the susceptibility of the strain and the risk of deterioration of renal function in the native valve, and the addition of rifampicin in the prosthetic valve).
- c) Severe IPPB caused by MRSA (or MSSA in patients with anaphylactic allergy to beta-lactams), especially if there is bacteremia, in monotherapy or associated with clindamycin or linezolid.
- d) Infection of the joint prosthesis or osteosynthesis material by *S. aureus* (MRSA or SASM), in doses of 8–10 mg/kg/day (Shariati et al., 2020).

Use of oral cotrimoxazole should be considered in the following circumstances:

- a) Mild or moderate IPPB produced by MRSA (or by SASM in allergic to beta-lactams), although in empirical treatment it should be remembered that its efficacy is not optimal when the infection is produced by beta-hemolytic streptococci of groups A, C or G.
- b) Infection of prosthetic material and in chronic osteomyelitis by MRSA (or by SASM in case of allergy to beta-lactams), as an alternative to linezolid, associated with rifampicin.

Clindamycin can be used in:

- a) Mild or moderate IPPB produced by MRSA (or by SASM in patients allergic to beta-lactams).
- b) As an alternative to linezolid in osteomyelitis and infection of prosthetic material caused by MRSA (or by SASM in patients allergic to beta-lactams).
- c) Pneumonia due to a strain of *S. aureus* that produces LPVT and IPPB due to an enterotoxin-producing strain (Khan et al., 2018).

Minocycline and doxycycline can be used as oral treatment alternatives for mild or moderate MRSA IPPB. Minocycline is more active, has a lower risk of resistance development, and is not metabolized through CYP3A4. Tigecycline is another alternative intravenous treatment of IPPB due to MRSA of moderate severity, especially when the infection is polymicrobial.

Use of rifampicin in staphylococcal infection is always in association and is indicated:

- a) Biofilms (infection on prosthetic material or bone sequestration) (Suresh et al., 2019).
- b) Growth of the microorganism in the vascular endothelium (persistent or recurrent bacteremia without focus).

The most commonly used antibiotics are quinolones, cotrimoxazole, and linezolid. The association with levofloxacin is the guideline of choice for the treatment of infection on osteoarticular prosthetic material by SASM (Otto, 2018).

Fosfomycin, like rifampicin, is used in association with other drugs with which it generally has a synergistic or additive behavior. The main indications are the following:

- a) infections in territories where the diffusion of the antibiotic is limited (CNS, eyeball, abscesses and other suppurative collections when drainage is difficult or incomplete).
- b) left endocarditis and MRSA infections with criteria of severe sepsis.
- c) infections of moderate or high severity caused by a MRSA strain with high limit susceptibility (MIC of vancomycin of 2 mg/L, daptomycin of 1 mg/L or linezolid of 4 mg/L).
- d) moderate or severe infections caused by a strain of SASM with a vancomycin MIC >1 mg/L (Davis et al., 2015).

Coagulase-negative staphylococci infections.

The antibiotic treatment of infections caused by most of the CoNS species (bacteremia and associated with foreign bodies) is similar to what was previously mentioned for those caused by *S. aureus*. As 80% of the species are resistant to methicillin, the antibiotics of choice are vancomycin, linezolid, and daptomycin. If the species is methicillin-susceptible, cloxacillin should be used. Vancomycin and daptomycin are preferred for bacteremia, and for infections associated with implant materials, linezolid or cotrimoxazole, associated or not with rifampin, unless the species is methicillin-susceptible, in which case the first option is rifampicin with levofloxacin.

S. lugdunensis and *S. schleiferi* are often susceptible to penicillins, and urinary tract infection due to *S. saprophyticus* can be treated with amoxicillin-clavulanate, a first-generation cephalosporin, cotrimoxazole, or oral nitrofurantoin (Heilmann et al., 2019).

Antimicrobial resistance

90% of *S. aureus* are resistant to penicillin produced by β -lactamases (blaZ gene). MRSA methicillin resistance phenotype is also frequent due to the acquisition of the *mecA* gene that encodes the penicillin-binding protein PBP2a that has low affinity for β -lactams. It implies resistance to all β -lactams, except ceftaroline and ceftobiprole. Currently in Spain it is 10–25%. They present nosocomial transmission, although lately also community transmission. It is associated with the MRSA CC398 clone that has a multidrug resistance phenotype. It is detected using 30 μ g cefoxitin discs: (a) *S. aureus* and *S. lugdunensis*, halo of ≤ 21 mm indicates the presence of the *mecA* gene. (b) CoNS, a halo of ≤ 24 mm indicates the presence of this gene (Bartash and Nori, 2017).

The phenotypic expression of methicillin resistance can be heterogeneous (MIC for oxacillin: 1–16 μ g/mL) or homogeneous (MIC >16 μ g/mL). Strains with heterogeneous expression are characterized by the fact that only a small proportion of the population ($\leq 0.1\%$) survives with oxacillin concentrations greater than 10 μ g/mL; they show great heterogeneity in the size of the colonies when grown on agar. In strains with homogeneous expression, most of the population expresses resistance and the size of the colonies is also homogeneous.

In 2011, a new methicillin resistance gene called the *mecC* gene was described with a 69% homology with the *mecA* gene: it presents strains resistant to ceftaroline (MIC >1 mg/L). It is associated with clonal complexes CC5, CC8, CC22. Screening is performed: cefoxitin <22 mm; MIC oxacillin >2 mg/L. It is confirmed when no *mecA* gene (GeneXpert) or PBP-2 agglutination is detected with PCR.

There are strains of *S. aureus* with low-level resistance or borderline resistance to oxacillin (borderline-oxacillin-resistant *S. aureus* or BORSA) that are characterized by intermediate resistance to oxacillin and MIC values of this antibiotic in the range 1–8 μ g/mL. Presents elevated oxacillin MIC without *mecC* gene-mediated resistance (Hryniewicz and Garbacz, 2017).

Staphylococcus strains have maintained a high susceptibility to glycopeptides, so that most strains are susceptible to vancomycin and teicoplanin. However, since 1997 the presence of strains of *S. aureus* with decreased susceptibility to vancomycin has been described in Japan. They are rare. It has been detected in the United States, Europe, South America and Asia according to:

- EUCAST: resistant if vancomycin/teicoplanin MIC >2 mg/L.
- CLSI:
 - Sensitive if vancomycin/teicoplanin MIC ≤ 2 mg/L.
 - Intermediate if MIC vancomycin/teicoplanin 4–8 mg/L.
 - Resistant if vancomycin/teicoplanin MIC ≥ 16 mg/L.

These strains were named vancomycin-intermediate *S. aureus* (VISA) with MIC 4–8 mg/L. They have poorly defined resistance mechanisms (Fu et al., 2020).

There are strains called vancomycin-resistant *S. aureus* (VRSA) with MIC ≥ 16 mg/L. Mediated by the *vanA* gene, located in transposon Tn1546. It is associated with clones CC5, CC8 and CC30 (Gardete and Tomasz, 2014).

Resistance of *Staphylococcus aureus* to other antibiotics

Macrolides: the presence of *erm* (A) and *erm* (C) genes generally confers a resistance phenotype called MLSB (resistance to group B macrolides, lincosamides and streptogramins) and this phenotype can be constitutive or inducible expression (cMLSB or iMLSB). In strains with the iMLSB phenotype, erythromycin induces the expression of the resistance mechanism (Feßler et al., 2018).

Aminoglycosides: the susceptible phenotype is the most frequent in staphylococci. Among the resistance mechanisms, the most frequent is that mediated by the *aac*-(6')-*aph*-(2'') gene. The strains appear resistant to gentamicin and tobramycin and susceptible to amikacin when a diffusion antibiogram is performed with discs. It is due to the action of modifying enzymes transmitted by plasmids or transposons (Nazarchuk et al., 2020).

Quinolones: the main mechanism of resistance to fluoroquinolones in staphylococci consists of mutations in the targets of action of the antibiotic, specifically in DNA topoisomerase IV (GrlA and GrlB) and in DNA gyrase (GyrA and GyrB). They are common in nosocomial MRSA strains.

Lipoglycopeptides (dalbavancin*, telavancin, oritavancin): Presents excellent activity against MRSA and multi-resistant. *On some occasions, there are strains with increased MIC (0.25–0.5 mg/L).

Oxazolidinones (linezolid): They are very rare. Mutations occur in 23S rRNA and ribosomal proteins. They are generally 100% susceptible. Resistance to this antibiotic has been observed both in vivo and in vitro in staphylococci, although it is rare in patients with prolonged treatment with this antimicrobial, by the dissemination of resistant clones in hospital units, or by the dissemination of transposons or plasmids that contain the gene *cfr* (Shariati et al., 2020).

Lipopeptides (daptomycin): They are very rare. It is produced by changes in the cell membrane and wall. They are active in 100% of the strains. Resistance (MIC >1 mg/L) could appear in infections such as osteomyelitis, endocarditis, devices, foreign bodies and poorly perfused tissues (Shariati et al., 2020).

Mupirocin: The CLSI does not define cut-off points to interpret susceptibility to this antibiotic. Two resistance phenotypes can be distinguished:

- Low level resistance (MIC 8–256 µg/mL) produced by *ileS* native gene mutations.
- High level resistance (MIC ≥ 512 µg/mL) by acquisition of plasmid containing the *mupA* gene.

In the first case, although it was initially considered to be clinically irrelevant resistance, it must be taken into account that these strains do present problems when using mupirocin for nasal decolonization. Regarding high-level resistance, this antibiotic is totally ineffective (Dadashi et al., 2020).

Tetracycline: resistance to tetracycline and doxycycline in staphylococci is quite frequent and may be due to two mechanisms: increased active expulsion and ribosome protection. The first mechanism is encoded by the *tetK* and *tetL* genes and the second by the *tetM* and *tetO* genes (Shariati et al., 2020).

In previous studies of colonization by MRSA, the susceptibility observed depending on the type of sample has been: 31–48% for pharyngeal exudate, 19–38% for perineal exudate, 78–82% for nasal exudate, 85–92% for nasal along with the pharyngeal, 88–93% the nasal along with the perineal, and 98% the triple nasal, pharyngeal and perineal intake. Therefore, a nasal swab is considered the most suitable sample if a single sample is chosen for surveillance cultures (Sakr et al., 2019).

Isolation usually lasts throughout admission or until at least three consecutive surveillance samples are negative. With greater agreement is the use of disposable gloves, masks and gowns when handling patients and always washing the hands of healthcare personnel after handling patients. Nasal decolonization with mupirocin with or without the use of chlorhexidine hygiene, restriction of the use of antimicrobials (cephalosporins and fluoroquinolones) and training of healthcare personnel.

The control of MRSA must combine better use of antimicrobials and epidemiological measures, including the detection of carriers, which reduces the pressure of colonization and, therefore, its transmission (Dadashi et al., 2020).

History and introduction

The first description of *Streptococcus pneumoniae* in the literature can be attributed to Klebs in 1875 and Eberth and Ma'tray in 1880. They later used the term "Pneumoniekokken" for their findings based on observations from sputum and lung fluid of pneumonia patients (White et al., 1938). The discovery of *S. pneumoniae* is, however, accredited to two scientists, George M. Sternberg in the United States and Louis Pasteur in France, who concurrently identified the organism in 1881. Both these scientists injected human saliva in rabbits; Sternberg used his saliva, whereas Pasteur inoculated saliva from a child who had died from rabies. Both of them identified and isolated diplococci in the blood of rabbits (White et al., 1938). In 1886, the organism was termed as "Pneumococcus" by Fraenkel (1886) due to its tendency to cause pulmonary disease. Based on its appearance on gram-stain, it was re-named *Diplococcus pneumoniae* in 1920 (Winslow et al., 1920) and finally in 1974, due to its morphological characteristics and ability to grow as cocci chains, the current name *Streptococcus pneumoniae* was allotted (Deibel and Seeley Jr., 1974).

S. pneumoniae normally colonizes the upper respiratory tract. It causes a variety of diseases in adults as well as in children, including lobar pneumonia, sinusitis, meningitis, and otitis media. It is a gram-positive diplococcus that grows in chains in liquid culture mediums. It is non-motile, non-spore-forming, and can ferment glucose to lactic acid (Bogaert et al., 2004).

Structure

S. pneumoniae is lancet-shaped, which means that the bacterium is pointed at one end. Single bacterium measures 0.5–1.25 µm in diameter (Todar, 2020). *S. pneumoniae* consists of an outer capsule, an inner cell wall, a periplasmic space, plasma membrane, cytoplasm, and nuclear material (DNA).

Capsule and serotypes

Most pneumococci consist of an external polysaccharide capsule (PSC); however, some non-encapsulated variants also exist (Keller et al., 2016). The capsule is almost 400 nm thick and accounts for more than half of the pneumococcal volume. It is made up of repeating oligosaccharides, which are synthesized in the cytoplasm and are transported to the surface of the bacteria by cell membrane transferases after polymerization. The capsular polysaccharide (CPS) is covalently linked to the outer peptidoglycan of the cell wall (Calix et al., 2012; Geno et al., 2015).

Multiple genes are responsible for CPS synthesis, which are present in a cassette-like arrangement (Griffith, 1928; Dawson, 1930). The capsule locus (*cps locus*) has type-specific genes in between the genes mutual to many or all pneumococci. This arrangement allows the recombinational exchange of genetic material and the formation of different serotypes (Coffey et al., 1998).

To date, 98 different types of CPS (serotypes) have been discovered, and two systems are used to classify these serotypes. The American system (less preferred), which enlists serotypes in the order of their discovery, and the Danish System (more preferred) in which similar, antigenically-related serotypes are grouped together (serogroups). Lower number serotypes were identified earlier due to their clinical relevance, and hence they were the first ones to be numbered. Serotypes are of significant importance due to their implication in current and new vaccines (Geno et al., 2015, 2017).

Cell wall

The Pneumococcal cell wall lies inner to capsule, has six layers, and is mainly composed of peptidoglycan covalently linked to teichoic acid. Peptidoglycan is made up of alternating N-acetyl-D-glucosamine and N-acetylmuramic acids arranged in long chains

(Fig. 1). The pneumococcal cell wall also contains lipoteichoic acids (LTA), which are similar to wall teichoic acids (WTA) except that they have a lipid part attached to them (Vollmer et al., 2019; Yamaguchi et al., 2019). WTA is attached covalently to peptidoglycan; in contrast, LTA is non-covalently linked to the cytoplasmic membrane with the help of a lipid anchor (Fischer, 2000). Both WTA and LTA contain phosphorylcholine as a structural component that binds choline-binding proteins. Phosphorylcholine plays an essential role in the virulence of the organism. C-polysaccharide is a component of the cell wall in all capsular pneumococci, and it is made up of teichoic acids and tightly attached peptidoglycan fragments. Cell wall plays a vital role in maintaining the bacterial shape, division, and growth. Components of the cell wall interact with the host, e.g., C-polysaccharide reacts with C-reactive proteins (CRP) and other acute-phase reactants during inflammatory processes. Elevated CRP levels are observed in pneumococcal infections, but it is a non-specific marker and is raised in many other infections (Vollmer et al., 2019; Yamaguchi et al., 2019).

Cytoplasmic structures and metabolism

Like other gram-positive bacteria, the *S. pneumoniae* cell membrane is a phospholipid bilayer, made up of proteins and lipids, chiefly phospholipids, but lack sterols. The protein-to-lipid ratio is approximately 3:1 and has lipoteichoic acid linked to the outer surface of membrane lipids. The cytoplasm is abundant in 70S ribosomes but lacks endospores (Salton and Kim, 1996).

S. pneumoniae is a fermentative bacteria that rely heavily on carbohydrate metabolism for energy, biosynthesis, and growth. However, the bacteria has numerous transporter systems (e.g., ATP-binding cassette transporters, phosphotransferase systems) and enzymes (e.g., glucokinase, transketolase) that enable it to use a variety of substrates such as amino acids, iron, and other compounds (Leonard and Lalk, 2018). The bacterial metabolism is regulated by Catabolite control protein A and CodY (nutritional regulator). An effective metabolic process is vital for the growth and survival of bacteria (Carvalho et al., 2011; Hendriksen et al. 2008).

Genome

The genome of *S. pneumoniae* consists of a closed, circular DNA containing 2.0–2.1 million base pairs along with small plasmids. The guanine-cytosine content makes up 39.7% of the genome. There are 1553 core genes that are essential for viability and an extra 154 genes in virulome, which play a role in the virulence of the organism. An additional 176 genes are responsible for maintaining a noninvasive phenotype. Up to 10% variation in the genome can exist between different strains of pneumococcus (Tettelin et al. 2001; Lanie et al., 2007; Van der Poll and Opal, 2009).

Pili

Pili are hair-like extensions from the surface of the bacteria and are made up of proteins called pilins. They extend out of PSC and are approximately 6 nm wide and over 1 µm long (Hilleringmann et al., 2009). Pili enhance the attachment of pneumococci to the epithelial lining (Barocchi et al., 2006).

Surface proteins

It has been estimated that pneumococcus has more than 500 surface proteins, either attached physically to cell wall or lipoproteins associated with the cell membrane (Todar, 2020). These surface proteins aid in the pathogenesis of bacteria and protect it against the

Fig. 1 Simplified view of *Streptococcus pneumoniae* cell wall and cell membrane. Adapted with permission from Brooks LR, and Mias GI (2018) *Streptococcus pneumoniae's* virulence and host immunity: Aging, diagnostics, and prevention. *Frontiers in Immunology* 9: 1366; Made from <https://smart.servier.com/>.

host's defense (Brooks and Mias, 2018). Surface proteins include (1) penicillin-binding proteins; (2) choline binding proteins (e.g., pneumococcal surface protein, autolysins, and CbpF); (3) metal-binding proteins; (4) LPXTG cell wall-bound proteins (e.g., neuraminidase); and (5) non-classical surface proteins (Brooks and Mias, 2018).

Important features

Transformation

S. pneumoniae is capable of natural transformation. Transformation is a process of horizontal gene transfer in which bacterium picks up genetic material (naked DNA) from the neighboring environment, or genetic material is transferred from one bacterium to another through surrounding media. This process was first shown by Griffith (1928). In natural transformation and recombination process, the beneficial mutations in bacteria are fixed and dispersed. Through transformation, mobile genetic elements are disseminated, and new genes are gained (Straume et al., 2015). The normal genetic exchange occurs between different co-existing strains of pneumococcus during nasopharyngeal colonization as pneumococcus has very high transformation efficacy in the nasopharynx (Marks et al., 2012). The process of transformation plays a crucial role in the evolution of genomes and the development of resistance against antibiotics and evading vaccines conferred immunity (Lattar et al., 2018).

During the transformation process, the pneumococcus enters a particular physiologic state of "competence" which is triggered by peptide pheromone called a competence-stimulating peptide (Johnsborg and Håvarstein, 2009). The state of competence can also be induced by factors that damage the DNA of the organism, such as mitomycin C, fluoroquinolone, and topoisomerase inhibitors (Gagne et al., 2013). Competence increases the resistance of *S. pneumoniae* to oxidative stress by increasing the repair of damaged DNA. The virulence and nasal colonization depend on intact competence system as the bacteria are successfully able to repair DNA damages produced by oxidative bursts (Salvadori et al., 2019).

Gram positivity

Streptococcus is a gram-positive bacteria. The peptidoglycan of the bacterial cell wall takes up crystal violet stain and appear purple under the microscope. Fig. 2A shows gram stained Pneumococci.

Culturing of pneumococcus

S. pneumoniae is a fastidious bacteria, i.e., it requires a specific environment and nutrients to grow. It grows best at 35–37 °C with 5% carbon dioxide. Usually, the bacteria are cultured on blood agar, but chocolate agar can also be used. Catalase (also present in the blood) is required for the growth of bacteria as it produces a large amount of H₂O₂. In blood agar, the doubling time of bacteria is 20–30 min (at 37 °C). The bacteria form small (~1 mm), grey, and moist or mucoid colonies with a zone of green (alpha) hemolysis (WHO and CDC, 2011; Todar, 2020). Pneumococci show phase variation where the opaque colonies turn transparent. The opaque phase is more suited for survival in the blood, whereas the transparent phase is a better fit for nasopharyngeal colonization (Li and Zhang, 2019). The young colonies of pneumococci appear raised, but after 24–48 h, flattened colonies with a depressed center are seen (Fig. 2C) (WHO and CDC, 2011). This happens when the central (older) bacteria start undergoing autolysis, thus leading to a depression in the center.

Alpha-hemolysis

S. pneumoniae (in aerobic conditions) and *S. viridans* are alpha-hemolytic, i.e., they produce a green or dark hue when cultured on blood agar (Fig. 2D). *S. pneumoniae* produces pneumolysin (previously called alpha-hemolysin), which produces greenish pigment on the breakdown of hemoglobin in blood or chocolate agar. Alpha-hemolysis is also called incomplete or partial hemolysis, and it is due to H₂O₂ produced by the bacteria which oxidize hemoglobin to methemoglobin (WHO and CDC, 2011). In anaerobic conditions, however, the bacteria can cause beta-hemolysis due to oxygen-labile hemolysin (Todar, 2020).

Optochin sensitivity

Optochin, also called ethylhydrocupreine hydrochloride, is used to differentiate *S. pneumoniae* from *S. viridans* group, which is also an alpha-hemolytic streptococcus. *S. pneumoniae* is optochin sensitive and will show a zone of inhibition (>14 mm) around the optochin disk (6 mm, 5 µg), whereas resistant bacteria (e.g., *S. viridans*) continue to grow without inhibition (WHO and CDC, 2011). Fig. 2E shows an example of optochin sensitivity test. In recent years optochin resistant *S. pneumoniae* has emerged (Nunes et al., 2008), thus reducing the reliability of the test.

Quellung reaction

Quellung reaction, also called Neufeld reaction (Neufeld, 1902), is used to determine the serotype of pneumococcus (Fig. 2F). Typing serum is added to bacteria and then observed under a microscope for capsular swelling, which happens due to the binding of

Fig. 2 Images showing different properties of *Streptococcus pneumoniae* (A) Gram staining of bacterial culture shows gram-positive, lancet-shaped diplococci; (B) Scanning electron microscopic image of *S. pneumoniae* depicts two, round-shaped cocci; (C) Doughnut-shaped *S. pneumoniae* colonies with depressed centers (black arrows). The colonies without depression are bacteria other than *S. pneumoniae*; (D) *S. pneumoniae* shows alpha hemolysis (green) on blood agar. Alpha hemolysis can also be produced by *S. viridians* group; (E) Optochin-sensitivity test shows *S. pneumoniae* on the left with a zone of inhibition around the optochin imbibed disc, i.e., optochin-sensitive, whereas, on the right side, optochin-resistant bacteria show uninhibited growth up to the edge of the disc; (F) Capsular swelling observed on Neufeld-Quellung test. Antibodies bind to the capsule of *S. pneumoniae*, which then appears thickened under the microscope. Source: (A) CDC/Arnold Kaufman; (B) CDC/ Dr. Richard Facklam; (C) CDC/ Dr. Richard Facklam; (D) Wikimedia/Netha Hussain; (E) CDC/Dr. Richard Facklam; (F) CDC. All images from CDC are available at PHIL.

the type-specific antibody with the CPS. The reaction can also be seen in other encapsulated organisms such as *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Escherichia coli* (WHO and CDC, 2011).

Catalase negative

Catalase breaks down H_2O_2 into H_2O and O_2 . The O_2 produced is visible in the form of bubbles in the liquid (Fig. 3A). Catalase test is used to differentiate between the members of gram-positive cocci. *S. pneumoniae* and *Enterococci* are catalase-negative, whereas *Staphylococci* are catalase-positive (WHO and CDC, 2011).

Fig. 3 (A) Illustration A shows the results of a catalase test. *S. pneumoniae* being catalase-negative will not produce bubbles on the slide; (B) Illustration B shows bile solubility test to identify *S. pneumoniae*. Since *S. pneumoniae* is bile soluble, when pneumococcus is added to the test tube containing bile salts, pneumococcal cells rupture. This makes the fluid clear, as seen in test tube 4. If any bile resistant bacteria are added to bile salts, bacterial cells do not rupture, and the fluid in test tube remains turbid as seen in test tube 2. Made using <https://smart.servier.com/>.

Bile solubility

Bile (sodium deoxycholate) solubility test is also used to differentiate *S. pneumoniae* from *S. viridans* group (Fig. 3B). Except for *S. pneumoniae*, all alpha-hemolytic streptococci are bile resistant (WHO and CDC, 2011).

Virulence factors

S. pneumoniae has numerous virulence factors in the form of physical structures, surface proteins, and toxins. All of these virulence factors help the bacteria in the invasion of the host and evading the body's immune response to cause disease (Jedrzejak, 2001). Therefore, it is essential to recognize the role played by these virulence factors to understand the pathogenesis of diseases caused by *S. pneumoniae*. Some of the most important virulence factors are shown in Fig. 4 and discussed below.

Capsule

The PSC of *S. pneumoniae* is regarded as its primary virulence determinant (Geno et al., 2015). CPS plays an integral part in nasopharyngeal colonization by reducing entrapment of *S. pneumoniae* in nasal mucus and subsequently evading the clearance by mucus ciliary flow. CPS aids in the access and attachment of *S. pneumoniae* to the surface of epithelial cells by repelling sialic acid-rich mucopolysaccharides present in the mucus (Nelson et al., 2007). It helps to evade the host's immune system by interfering with both the classic and alternative complement pathways. CPS can also attenuate the interaction between the bound C3b/iC3b or Fc regions of immunoglobulin on the bacterial cell surface and surface receptors of phagocytic cells thus inhibiting opsonization (Hyams et al., 2010; Abeyta et al., 2003).

Cell wall

S. pneumoniae, being a gram-positive bacteria, has a thick cell wall comprising of peptidoglycan along with LTA and WTA. Human lysozyme is an antimicrobial protein that helps the degradation of the bacterial cell wall by enzymatically targeting the bond between N-acetyl-d-glucosamine and N-acetylmuramic acid, thus breaking the integrity of peptidoglycan (Ganz and Lehrer, 1997). *S. pneumoniae*, to resist this bactericidal action, undergoes secondary modification in its glycan chains rendering the target moieties unrecognizable by lysozymes (Bui et al., 2012). WTA, LTA, and peptidoglycan are identified as pathogen-associated molecular patterns (PAMPs) by the host's immune system and elicit an inflammatory response. The inflammatory response caused by LTA is possibly carried out by the activation of the C-type lectin pathway of complement (Gisch et al., 2013).

Choline-binding proteins

Choline binding proteins (CBPs) are pneumococcal surface protein found anchored to phosphorylcholine residue present in the cell wall (Gosink et al., 2000). CBPs hinder both the innate and adaptive immune system by blocking the activation of the complement system and attenuating the ability of immunoglobulin to clear the bacteria. *S. pneumoniae* has approximately 10–16

CBPs present on its cell wall, including Pneumococcal surface protein A (PspA), Pneumococcal surface protein C (PspC), and LytA (Bergmann and Hammerschmidt, 2006).

Pneumococcal surface protein A (PspA)

PspA inhibits opsonization of *S. pneumoniae* by binding to complement (Jedrzejewski et al., 2001). PspA also binds to apolactoferrin (an iron-depleted form of lactoferrin) and protects the pathogen from the bactericidal effect of apolactoferrin (Shaper et al., 2004).

Pneumococcal surface protein C (PspC)

PspC plays a significant role in adhesion and nasopharyngeal colonization of *S. pneumoniae* by binding to the polymeric immunoglobulin receptors present on epithelial cells (Rosenow et al., 1997). Additionally, it also blocks the alternative pathway in the host cell by binding to factor H, thus interfering with opsonization (Dave et al., 2004).

LytA

LytA is an autolysin that causes bacterial cell lysis and release of intracellular products like pneumolysin, inflammatory peptidoglycan, and teichoic acids (Kadioglu and Andrew, 2004).

Immunoglobulin A1

Immunoglobulin A1 (IgA1) protease is a zinc metalloprotease secreted by *S. pneumoniae* to target and cleave human immunoglobulin A1 (IgA1) (Chi et al., 2017). The IgA1 isotype comprises more than 90% of the total IgA in the human airway (Wani et al., 1996). Thus, through the action of IgA1 protease, the humoral protection and inflammatory response offered by IgA1 on mucosal surfaces is hampered.

Pneumolysin

Pneumolysin is a potent toxin secreted by *S. pneumoniae*. It belongs to a family of cholesterol-dependent cytolysins and exerts its main cytolytic effect by forming pores on cholesterol-containing cell membranes (Marshall et al., 2015). Pneumolysin activates the classical complement pathway and causes a subsequent decrease in C3b opsonization (Paton et al., 1984; Mitchell and Dalziel,

2014). Pneumolysin exerts its proinflammatory effect by activating Toll-like receptor (TLR)-4 (TLR-4) and stimulating cytokine and chemokine production (Van der Poll and Opal, 2009; Los et al., 2013; Steel et al., 2013).

Metal-binding proteins

Metal-binding proteins are lipoproteins that bind to ATP-binding cassette transporter and help metal ions such as iron, zinc, and manganese to be transported across membranes by utilizing energy generated from ATP binding and hydrolysis (Brooks and Mias, 2018). These metal ions are vital for the survival and growth of bacteria, especially in conditions when free ions in the host are low. The four most crucial metal-binding proteins are described below.

Pneumococcal surface adhesin A (PsaA)

PsaA is involved in the transport of magnesium and zinc into the cell (Rajam et al., 2008). Mutations that hamper the ability of PsaA to obtain manganese can cause decreased resistance of *S. pneumoniae* to oxidative stress (Mitchell and Mitchell, 2010).

Pneumococcal iron acquisition A (PiaA), pneumococcal iron uptake A (PiuA), and pneumococcal iron transporter (PitA)

PiaA, PiuA, and PitA are involved in iron transport and uptake (Whalan et al., 2005, 2006). Mutations in PiaA and PiuA can inhibit the growth and virulence of *S. pneumoniae* (Brown et al., 2001; Honsa et al., 2013).

LPXTG-anchored proteins

LPXTG-anchored proteins are cell surface proteins that contain an LPXTG motif (X denotes any amino acid). They are linked covalently to the bacterial cell wall by sortase. Sortase transpeptidase recognizes the particular amino acid sequence present in LPXTG protein. After recognition, it cleaves and anchors the protein to the cell wall.

Neuraminidase is an LPXTG-anchored protein that cleaves terminal sialic acid from glycoprotein, glycolipid, and oligosaccharides present on the host's cell surface and exposes new potential receptors for binding (Mitchell and Mitchell, 2010). Furthermore, the removal of sialic acid from lactoferrin can impede its bactericidal effect (Brooks and Mias, 2018). Neuraminidase also plays a pivotal role in nasopharyngeal colonization and pathogenesis of otitis media (Wren et al., 2017).

Pili

Pili promotes colonization of pneumococcus in the host's nasopharynx and lungs by helping it to bind human epithelial cells (Barocchi et al., 2006; Steel et al., 2013). It can also aid bacteria in evading phagocytosis by immune cells (Van der Poll and Opal, 2009) and can stimulate the release of large amounts of proinflammatory cytokines, e.g., large amounts of tumor necrosis factor (TNF) (Barocchi et al., 2006).

Non-classical surface proteins

Non-classical surface proteins (NCSPs) are a miscellaneous group of proteins that lack attachment to the membrane via leader peptide or anchor motif. They perform several functions and hence given the name moonlight proteins (Bergmann and Hammerschmidt, 2006). NCSPs include pneumococcal adhesion and virulence A (PavA) and glycolytic enzymes.

Pneumococcal adhesion and virulence A (PavA)

PavA is an adhesin present on the outside of the *Pneumococcus* cell wall. It binds to fibronectin and mediates adherence to cells of the host. PavA plays a major part in virulence, and it has been observed that the load of bacteria in the host considerably decreases when PavA is not present (Holmes et al., 2001).

Glycolytic enzymes

Glycolytic enzymes such as enolase and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) are also NCSPs that mediate their virulence by binding to and stimulating host's plasminogen on the pneumococcal surface. Enolase is found on the surface of pneumococcus, while GAPDH is found on the surface as well as in the cytoplasm (Kolberg et al., 2006; Bergmann et al., 2004). Enolase binds to plasminogen and helps *S. pneumoniae* to adhere to host cells, disseminate, and avoid the host's immune cells (Bergmann et al., 2013). GAPDH can bind to hemoglobin and is postulated to play a part in the attainment of iron for the bacteria (Zomer et al., 2015).

Epidemiology

The incidence of pneumococcal infection varies in different populations and age groups. *S. pneumoniae* colonization may be asymptomatic or can cause mucosal and invasive infections (WHO, 2018). *S. pneumoniae* is the leading cause of severe pneumonia and associated mortality worldwide, and it is the most common cause of bacterial pneumonia in children (WHO, 2018; WHO, 2019).

In 2015, over 9 million pneumococcal infections were recorded with >318,000 deaths in children under five years. Most of these deaths occurred in developing countries. Global incidence and mortality rate of pneumococcal pneumonia in children under-five was 1356 per 100,000 and 36 per 100,000, respectively (Wahl et al., 2018). *S. pneumoniae* is the most common cause of community-acquired pneumonia, accounting for almost a quarter of all identified cases (Said et al., 2013). In the United States, it has been estimated that each year almost 502,600 cases of non-bacteremic pneumococcal pneumonia, 29,500 cases of invasive pneumococcal disease (IPD), and 25,400 pneumococcal-related deaths occur (Weycker et al., 2010). The occurrence of IPD is age-related, with more cases occurring in individuals above 50 years (Drijkoningen and Rohde, 2014). In Europe, the incidence rates of IPD range from 11 to 27 per 100,000 population, whereas in North America, the incidence rate is estimated to be 15–49 per 10,000 (Kyaw et al., 2003; Reinert et al., 2005; Lynch and Zhanel, 2009). Patients suffering from comorbidities like diabetes, lung, heart, or liver disease are at higher risk of pneumococcal disease (Zhang et al., 2018).

Pathogenesis

Colonization and transmission

S. pneumoniae is a commensal of the nasopharynx. In humans, colonization begins within the first week of life, increases in the initial few years, and then decreases as age progresses. In children, rates of colonization vary between 27–65% but can be as high as up to 90% (Yahiaoui et al., 2016; Smith et al., 2020). Less than 10% of adults are carriers of pneumococcus (Smith et al., 2020). Usually, one serotype exists at a time in most individuals, but the co-existence of multiple serotypes is also possible (Hare et al., 2008). Along with the rate, the duration of pneumococcal carriage also decreases with age (Högberg et al., 2007). Over-crowding (e.g., in daycares), lower socioeconomic status or poverty, respiratory viral infections, smoke exposure either due to smoking or cooking fires, and recent antibiotic use increases the risk of colonization (Van der Poll and Opal, 2009; Koliou et al., 2018). Changes in the natural biome of nasopharynx can also influence colonization as microbes compete for binding sites and nutrients (Van der Poll and Opal, 2009; Shak et al., 2013).

S. pneumoniae is mainly transmitted via respiratory droplets and secretions produced by coughing or sneezing of a carrier or infected individual. Also, transmission through fomites is possible when inanimate objects are contaminated with biofilms by chronic carriers (Marks et al., 2014). The transmitted bacteria can either be cleared by host defense or produce disease.

Body defense against infection

The elimination of bacteria depends on the host's immune system. The host's body fights off pneumococcal invasion by innate (early) and adaptive (late) immune system. After colonization, pneumococcus comes in contact with the host's epithelial lining (e.g., in the respiratory tract). The body tries to remove the bacteria via mucociliary clearance. The mucous traps the bacteria, and cilia beat to expel it. Epithelial cells produce antimicrobial peptides that can directly kill bacteria and secrete cytokines that recruit inflammatory cells (neutrophils and macrophages).

PAMPs are recognized by TLRs (e.g., TLR-2, TLR-4, and TLR-9), leading to stimulation of adaptive immune system cells. TLR-2 recognizes and binds to components of the pneumococcal cell wall (lipoproteins and peptidoglycan), and TLR-4 recognizes pneumolysin. TLRs are activated by recognition and binding of PAMPs, and this leads to the production of cytokines and co-stimulatory molecules, which eventually activate T cells. Antigen-presenting cells present (bacterial) antigen to T cells via major histocompatibility complex-II (MHC-II). T cells differentiate into Th1 and Th2 cells that produce interferons (IFN- γ) and interleukins, which provide signals for B cell maturation, further macrophage activation, and neutrophil recruitment. All these steps aid in the elimination of pathogens from the body (Brooks and Mias, 2018; Weiser et al., 2018; Henriques-Normark and Tuomanen, 2013; Loughran et al., 2019).

Invasion and disease

Using wide array of virulence factors, *S. pneumoniae* is able to evade host's immune response, decrease clearance, and cause infection. If the bacteria successfully escape host defense, it replicates and disrupts normal, non-pathogenic flora of the respiratory system (Van der Poll and Opal, 2009). *S. pneumoniae*'s negatively charged capsule avoids mucous entrapment. The bacteria secrete neuraminidase that cleaves mucin and provides sites for bacterial attachment as well as decrease mucociliary clearance. *S. pneumoniae* firmly adheres to epithelial cells using pili and CBPs (Löflying et al., 2011; Henriques-Normark and Tuomanen, 2013). *S. pneumoniae* also produces pneumolysin and H₂O₂, which forms pores and disrupts epithelium leading to infection of sterile organs and tissues. Pneumolysin inhibits cilia on respiratory epithelial cells, lyse host cells, and trigger inflammation via complement activation. It is also toxic to cochlear hair cells and contributes to otitis media. The bacteria can infect lungs (pneumonia), ear (otitis media), paranasal sinuses (sinusitis), and seed into the blood leading to sepsis, meningitis, and other complications as shown in Fig. 5 (Henriques-Normark and Tuomanen, 2013; Subramanian et al., 2019). *S. pneumoniae* uses phosphorylcholine (in the cell wall) to gain access to blood using the platelet-activating factor receptor (PAF-R). Binding of phosphorylcholine to PAF-R initiates uptake of bacteria in the vacuole (receptor-mediated endocytosis) to be transported across host cells into the bloodstream (Radin et al., 2005).

Fig. 5 Illustration showing colonization of nasopharynx by *S. pneumoniae* and progression to diseased states. *S. pneumoniae* colonizes the nasopharynx and is unable to cause disease in the presence of strong host defense; thus the individual remains asymptomatic. If the host immune system is weak, pneumococcus can invade into different sterile tissues and organs to cause diseases such as pneumonia, otitis media, sinusitis, and conjunctivitis. If the bacteria enters the bloodstream, it is known to cause meningitis, endocarditis, pericarditis, septic arthritis, osteomyelitis, and peritonitis. Made using <https://smart.servier.com/>

Meningitis develops when the pneumococcus can enter into CSF via choroid plexus or by crossing the blood-brain barrier (BBB) in cerebral capillaries. It is a two-step process. Initially, bacterial PspC binds to endothelial laminin receptor. Secondly, phosphatidylcholine binds to PAF-R, and bacteria translocate across BBB by receptor-mediated endocytosis. Once inside the CSF, pneumococcus can trigger an inflammatory response and cause neuronal damage and mediate meningitis (Orihuela et al., 2009; Henriques-Normark and Tuomanen, 2013; Loughran et al., 2019).

Diseases

Community-acquired pneumonia

Community-acquired pneumonia (CAP) causes significant clinical and economic burden of disease in both developed and developing nations and is a cause of considerable morbidity and mortality (File Jr and Marrie, 2010; Shibl et al., 2010). The most common pathogen which causes CAP is *Streptococcus pneumoniae*, independent of age (Drijkoningen and Rohde, 2014; Howard et al., 2005).

The clinical presentation of pneumococcal pneumonia is highly variable. Classically, pneumonia is characterized by the acute onset of chills and pleuritic chest pain followed by fever, fatigue, dyspnea, cough, sweats, and the production of purulent rusty color sputum (Brandenburg et al., 2000). However, these symptoms are more apparent and well-defined in younger patients as compared to older patients. In the older population, patients having pneumococcal pneumonia can be afebrile and disoriented with no other specific signs and symptoms. Usually, elevated respiratory rate is the only sign speculative of respiratory disease (Metlay et al., 1997). This puzzling clinical presentation often makes the diagnosis of CAP in the elderly a diagnostic conundrum.

The diagnosis of pneumococcal CAP starts with establishing the presence of pneumonia with the help of symptoms, clinical examination, and chest radiographs. The chest radiograph shows air space consolidation and infiltrates in one or more segments in a lobe (Janoff and Musher, 2015). Fig. 6 shows an image of a chest radiograph of pneumonia patient. Gram staining of sputum is regarded as a traditional and reliable test. The test strongly suggests positive for pneumococcus pneumonia, if it demonstrates high-quality (<10 squamous epithelial cells and >25 polymorphonuclear cells at a magnification of 100×) and predominance of gram-positive diplococci (Murray and Washington, 1975; Musher et al., 2004).

The detection of streptococci from blood and pleural fluid, which are otherwise sterile tissues, provide a definite diagnosis of pneumococcal pneumonia. However, less than 10% of patient who have pneumococcal pneumonia test positive for presence of streptococci in their blood, making the clinical usefulness of these tests very restricted (Luna et al., 2000). The main drawbacks of diagnosing CAP with the conventional microbiological investigation is its extensive time frame to isolate the bacteria and determine its antibiotic susceptibility, inadequate sampling, and high rate of a false negative.

Fig. 6 Chest X-ray (anteroposterior view) showing pneumonia of left lower lobe with some consolidation. Source: CDC/Dr. Thomas Hooten. *Image is available at PHIL.*

One of the diagnostic methods recently gaining momentum is a rapid immunochromatographic assay to detect C-polysaccharide of the pneumococcal cell in urine (Binax NOW *S. pneumoniae* assay). Children showed poor specificity for Binax NOW *S. pneumoniae* assay, mainly due to a higher rate of nasopharyngeal carriage and subsequent urinary excretion of teichoic acid (Charkaluk et al., 2006). In contrast, in the adult population, the sensitivity and specificity for Binax NOW *S. pneumoniae* assay were considerably high, especially in bacteremic patients (Sinclair et al., 2013). Prior antibiotic use has less influence on the diagnosis of this test (Said et al., 2013); however, the test can become false positive because of immunization (Navarro et al., 2004) and stays positive even one month after infection (Marcos et al., 2003).

For molecular testing, using polymerase chain reaction (PCR) assay of blood and respiratory tract specimens to detect specific *S. pneumoniae* targets e.g., *lytA*, *pneumolysin*, and *PsaA*, has shown promising results (Abdeldaim et al., 2008; Albrich et al., 2012).

Pneumonia caused by pneumococci that are susceptible or intermediately resistant to penicillin responds to treatment with penicillin, 1 million units intravenously every 4 h; ampicillin, 1 g every 6 h; or ceftriaxone, 1 g every 24 h (Janoff and Musher, 2015).

Acute otitis media

S. pneumoniae is the most common pathogen to cause otitis media (Ngo et al., 2016). Acute otitis media is characterized by otalgia, otorrhea, fever, vomiting, and the presence of fluid in the middle ear (Schilder et al., 2016). It is one of the most common bacterial infections in children between the ages of 6 months to 3 years (Klein, 2000). Otitis media has also been described as the leading cause of physician visits and antibiotic prescription in children (Zhou et al., 2008; Coco et al., 2009), and cause a significant strain on health care systems worldwide due to its chronicity, recurrence, and repeated antibiotic prescriptions.

The conversion of harmless nasopharyngeal colonization of pneumococcus to middle ear inflammatory disease is usually attributed to a concomitant upper viral respiratory infection (Heikkinen and Chonmaitree, 2003). The viral infection can cause eustachian tube obstruction, nasal mucosa alterations, and fluid retention, facilitating the entry of microorganisms to the middle ear and triggering otitis media.

On physical examination, the tympanic membrane is erythematous, with loss of light reflex and decreased mobility. Otitis media is usually diagnosed clinically by tympanic membrane visualization and testing hearing function (Vergison et al., 2010). If the tympanic membrane ruptures, a specimen of the exudate can be analyzed with gram staining and culture that would show the presence of gram-positive diplococcus streptococci. Otitis media in children is usually treated by a 7–10 days regimen of oral broad-spectrum antibiotics, usually amoxicillin. Guideline of the American Academy of Pediatrics suggests that otitis media in older children can be managed symptomatically. On the other hand, otitis media in infants is best managed with antibiotic therapy (Lieberthal et al., 2013). In the case of bacterial resistance or failure to resolve, amoxicillin-clavulanate and cefdinir can also be used (Coco et al., 2010).

Sinusitis

Acute bacterial rhinosinusitis is inflammation of the paranasal sinuses, usually maxillary sinus, due to bacterial infection (Rosenfeld et al., 2015). The most common pathogens causing the disease are *S. pneumoniae* and *H. influenzae* (Gwaltney Jr et al., 1992; Brook, 2002). Viral infection, allergens, and environmental pollutants can impair mucociliary clearance, which results in stasis of mucus and bacterial proliferation in the sinus (Gwaltney Jr et al., 1992, 1994).

Symptoms include purulent nasal discharge, nasal congestion, facial pain, and slight anosmia. Diagnosis is usually made based on clinical symptoms and findings. Treatment is mostly symptomatic because it is usually self-limiting.

Antibiotics can be prescribed if the infection persists, a 5–10 days regimen of amoxicillin is the standard therapy. Patients having a penicillin allergy are usually prescribed trimethoprim/sulfamethoxazole or a macrolide as an alternative (Rosenfeld et al., 2015).

Meningitis

Meningitis is the inflammation of the meninges and subarachnoid space, which can extend to involve the cortex and parenchyma of the brain as well. Meningitis can be caused by an infectious (bacterial, viral, or fungal) or non-infectious (autoimmune, drugs, or neoplasia) etiology. In nearly 70% of the cases of bacterial meningitis, the causative pathogen is *S. pneumoniae* and is associated with the highest rates of mortality (30%) and morbidity (Schedl et al., 2002; van de Beek et al., 2016). *S. pneumoniae* can reach the meninges and subarachnoid mainly through two routes: (i) Hematogenous spread and (ii) Spread from contiguous infected sites, e.g., paranasal sinuses or middle ear.

Pneumococcal meningitis cannot be differentiated from other causes of bacterial meningitis solely based on clinical manifestation. All patients of bacterial meningitis present with similar symptoms such as headache, fever, neck stiffness, and impairment of consciousness (Glasgow Coma Scale <14). The “classical” triad of meningitis (fever, neck stiffness, and altered mental status) occurs only in almost one-third of the patients. The involvement of brain parenchyma and cortex can cause focal neurological deficits and behavioral changes (Bijlsma et al., 2016). A petechial rash, which has been considered the hall-mark of meningococcal infection, can occur in pneumococcal meningitis as well (van de Beek et al., 2004). The physical examination will reveal neck stiffness, positive Kernig sign, and Brudzinski sign; however, the accuracy of these signs in identifying patients of meningitis is a topic of debate (Thomas et al., 2002).

Microbiological diagnosis of pneumococcal meningitis is made by gram staining and culture of CSF (Dunbar et al., 1998). However, it is clinically pertinent to point out that if a patient presents with a new CNS lesion, focal neurological deficit, or onset of seizures, cranial imaging (by CT scan) might be warranted before lumbar puncture to rule out elevated intracranial pressure. Antibiotics taken before the collection of CSF specimens can decrease the diagnostic sensitivity of the specimen. PCR of CSF can be a valuable tool, especially in those patients in which prior antibiotic intake has rendered gram stain and culture-negative (Châtelet et al., 2005). Latex agglutination testing in CSF has also been used for the rapid identification of *S. pneumoniae*, although its sensitivity is still variable (Brouwer et al., 2010).

Pneumococcal meningitis can be treated with 12–24 million units of penicillin every 24 h or 1–2 g ceftriaxone every 12 h. This regimen can successfully treat antibiotic-susceptible *S. pneumoniae*. For the resistant *S. pneumoniae*, β -lactam antibiotics are less likely to reach therapeutic levels in CSF and eradicate the pathogen. Thus vancomycin is included along with a β -lactam until susceptibility results are reported (Young and Thomas, 2018).

Unusual manifestations of pneumococcal infections

Before the advent of antibiotics or routine immunization with pneumococcal vaccine, unusual pneumococcal diseases were not uncommon. Albeit, their incidence has rapidly declined over the years, few cases can still be seen in clinical practice (Sousa et al., 2018). The unencapsulated type of *S. pneumoniae* has been implicated in causing epidemics of conjunctivitis (Martin et al., 2003). Endocarditis due to *S. pneumoniae* is a rare manifestation and usually occurs in patients who otherwise have healthy heart valves (Daudin et al., 2016). Another rare and potentially fatal cardiac disease caused by pneumococcus is purulent pericarditis (Zmora et al., 2019). *S. pneumoniae* can also cause osteoarthritic complications like septic arthritis and vertebral osteomyelitis (Suzuki et al., 2013; Dernoncourt et al., 2019). Spontaneous bacterial peritonitis (SBP) can also occur due to *S. pneumoniae*, while the bacteria are not part of normal gastrointestinal flora, it is postulated that SBP occurs due to primary respiratory tract infection like pneumonia and consequently bacteremia (Capdevila et al., 2001).

Risk factors for pneumococcal infections

The extremes of age are associated with increased risk of pneumococcal infection, children under the age of two years, and the elderly (>65) have the highest incidence of IPD. The increased susceptibility for *S. pneumoniae* in infants is usually due to their naive

immune system, while in elderly is due immunosenescence; a phenomenon in which the effectiveness of adaptive immune system declines with age leaving individuals disposed to a variety of infections (Infante et al., 2015; Krone et al., 2014).

In healthy children, crowded households and exposure to cigarette smoke are crucial risk factors for developing IPD (Pereiró et al., 2004). In non-elderly immuno-competent adults, cigarette smoking is one of the strongest risk factors for IPD (Nuorti et al., 2000). Alcohol abuse has also been described as one of the most common preventable risk factors for developing IPD (Grau et al., 2014). The incidence of IPD also increases with pre-existing comorbidities such as congestive heart failure (Kyaw et al., 2003), chronic lung disease (Kyaw et al., 2005), asthma (Talbot et al., 2005), and diabetes mellitus (Musher et al., 2000).

Individuals with a weakened immune system have a greater risk of developing IPD (Wong et al., 1992; Picard et al., 2003). Acquired disorders causing immune deficiency and increased risk of IPD are malignancy (Kyaw et al., 2003), HIV (Feldman and Anderson, 2016) and asplenia (Bisharat et al., 2001; Schutze et al., 2002).

Similarly, inherited immune deficiencies like Bruton's X-linked agammaglobulinemia and hemoglobinopathies e.g., sickle cell disease, carry a greater risk of IPD (Battersby et al., 2010).

Antibiotic resistance

In the early 1940s, the treatment of *S. pneumoniae* was straightforward, with the bacteria being highly susceptible to penicillin. In 1967, the first resistant isolate of *S. pneumoniae* was isolated, and to date, numerous strains with varying antibiotic resistance have made the treatment of pneumococcal disease increasingly multifaceted (Appelbaum, 2002).

Penicillin was first discovered in 1928, and for two decades after its discovery, *S. pneumoniae* was highly susceptible to it. In 1967, the first nonsusceptible *S. pneumoniae* strain was isolated, and this resistance was attributed to the alteration of penicillin-binding proteins, which were the prime target of the drug (Hansman, 1967). Similarly, resistance to other class of antibiotics (e.g., cephalosporins and macrolides) have also emerged raising concern about the use of these agents in the empiric treatment of clinical diseases frequently caused by the pneumococcus (Jorgensen et al., 1994). Pneumococcal isolates resistant to erythromycin, azithromycin, and clarithromycin have been isolated and are increasing at a steady rate (Jenkins and Farrell, 2009). Fortunately, *S. pneumoniae* resistance to fluoroquinolone is considerably low as of now.

The resistance of *S. pneumoniae* to a plethora of antibiotics poses a severe and grave health concern. With resistance to a large number of drugs, minor infections can lead to considerable mortality and morbidity. Thus, it is imperative to form strict guidelines for antibiotic use in the health sector. Awareness should be spread among the masses about the dire consequences of the misuse of antibiotics. Implementation and enhancement of pneumococcal conjugate-vaccines (PCV) and the development of other therapeutic regimens for the treatment of pneumococcal infections should be encouraged.

Vaccination for prevention

Vaccines play a chief role in the prevention of pneumococcal diseases. Currently, two types of subunit vaccines (conjugate and polysaccharide) are used in clinical practice. Pneumococcal conjugate vaccine (PCV) contains polysaccharide antigens conjugated with a carrier protein (e.g., diphtheria toxoid). Examples of PCV include PCV7 (Pneumovax®), PCV10 (Synflorix®; Fig. 7), and PCV13 (Pneumovax 13®) (Kim et al., 2017). PCV13 contains polysaccharides of the 13 most common pneumococcal serotypes and is currently recommended for use in the US and other parts of the world (CDC, 2019; Van Werkhoven and Huijts, 2018). These vaccines have reduced the burden of childhood pneumococcal diseases, especially the incidence of pneumococcal pneumonia has markedly decreased after the use of PCV13 (Olate et al., 2017; Takeuchi et al., 2020).

Pneumococcal polysaccharide vaccine (PPSV) uses capsule components as antigen. PPSV23 protects against 23 serotypes and reduces the risk of IPD in the elderly (CDC, 2019; Van Werkhoven and Huijts, 2018). PCV13 causes a T cell-dependent immune response that is stronger and long-lasting whereas, PPSV23 does not contain conjugated protein and therefore causes a T cell-independent response, which is weaker and requires booster (Kim et al., 2017). Table 1 shows the comparison between PCV and PPSV.

Both PCV and PPSV are age and serotype-dependent, and guidelines for vaccine use differ in different countries. In the US, PCV13 is recommended for children <2 years, whereas in elderly, smokers, immunocompromised, and individuals with selected comorbidities, PPSV23 is also given with PCV13 (CDC, 2019). A booster dose is usually recommended for (1) elderly >65 years who were vaccinated >5 years ago, (2) elderly >65 years who received vaccination when they were younger than 65, and (3) individuals between 2–64 years who are at increased risk of infection due to asplenia, HIV infection, or receiving immunosuppressive/cancer chemotherapy (Levinson, 2014).

Newer vaccines such as whole-cell vaccine (containing all bacterial components) and protein-based vaccines (e.g., PspA or pneumolysin) are being developed to reduce the burden of disease. The aim is to provide immunity against serotypes not covered by prior mentioned vaccines (Masomian et al., 2020).

Fig. 7 Pneumococcal conjugate vaccine 10 (PCV10) available under tradename Synflorix™. It contains polysaccharides of serotypes 1, 4, 5, 6B, F, 9V, 14, 18C, 19F, and 23F conjugated to carrier proteins (CP) such as tetanus toxoid CP, protein D, and diphtheria toxoid CP. Synflorix™ vial contains four doses and is administered intramuscularly. Courtesy of Dr. Dilshad Ahmed.

Table 1 Summary of vaccines used in clinical practice.

Pneumococcal vaccine	Example		Mode of action	Recommended populations	Strength	Weakness
	Names	Serotypes covered				
Conjugate	PCV7	4, 6B, 9V, 14, 18C, 19F and 23F	T cell-dependent activation of immune system.	Children <2 years.	Immunity lasts longer.	Expensive and limited serotype coverage.
	PCV10	1, 4, 5, 6B, 7F, 9V, 14, 18C, 19F and 23F		Children (≥ 2 years) and adults with specific medical conditions.	Protective against pneumonia and IPD.	
	PCV13	PCV10 serotypes + 3, 6A, and 19A			Reduces nasopharyngeal carriage.	
Polysaccharide	PPSV23	1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, and 33F	T cell-independent activation of immune system.	Elderly >65 years.	Wider serotype coverage.	Immunity is short-lasting compared to PCV.
				Individuals between the age of 2-64 years with specific medical conditions. Smokers between the age of 19-64 years.	Reduces the severity of pneumonia and protective against IPD.	Has limited to no effect on nasopharyngeal carriage.

Introduction

The genus *Streptococcus* is a group consisting of various Gram-positive cocci that are usually arranged in pairs or chains. Most species are facultative anaerobes, and some of them grow only in an atmosphere enriched with carbon dioxide (caphnophilic growth). Their nutritional requirements are complex, and their isolation requires the use of media enriched with blood or serum. They are able to fermenting carbohydrates, a process that produces lactic acid, and are catalase-negative. There are species that are important pathogens for humans, but most of them are commensal, members of the normal human skin and mucosal microbiota (Milagrosa and García Arenzana, 2007).

They can be classified in three ways:

- (a) Serological properties: Lancefield groups (originally, A to W).
- (b) Hemolytic patterns: complete hemolysis (beta), incomplete hemolysis (alpha), and no hemolysis (gamma).
- (c) Biochemical properties.

From a practical point of view, streptococci can be divided into two groups:

- β -hemolytic streptococci, which are classified according to Lancefield groups.
- α -hemolytic and γ -hemolytic streptococci, which are classified by biochemical tests. The latter group is collectively called streptococci viridans.

In this chapter the most important *Streptococcus* species that cause human diseases will be analyzed.

Streptococcus pyogenes

Streptococcus pyogenes is an important human-specific bacterial that causes a wide range of clinical manifestations from mild localized infections to life-threatening invasive infections. It is commonly associated with skin or throat infections (Ibrahim et al., 2016).

Etiology

S. pyogenes is a Gram-positive, catalase-negative, β -hemolytic *Streptococcus*. The type A antigen of *S. pyogenes* is a polysaccharide consisting of *N*-acetylglucosamine attached to a rhamnose polymer main chain (Cunningham, 2000).

This microorganism usually colonizes the pharynx, anus and genital mucosa. Transmission can occur through airborne droplets, hand contact with nasal secretions or with objects or surfaces contaminated with bacteria, skin contact with contaminated lesions or contaminated food sources (Murray et al., 2013).

Epidemiology

Skin lesions are the most important risk factor, but also the presence of a number of preexisting medical conditions increases the risk of invasive group A streptococcal disease, like diabetes, heart disease, neoplasms, injection drug users and poor living conditions.

Overall, *S. pyogenes* disease is due to newly acquired strains that cause infection of the pharynx or skin before specific antibodies are produced or the competing microorganisms are able to proliferate. *S. pyogenes* pharyngitis is a disease that primarily affects children between 5 and 15 years old, although infants and adults are also vulnerable to this entity. The transmission is mainly person to person via respiratory droplets. Overcrowding, such as in classrooms and day care centers, increases the likelihood of spread of the microorganism, especially during the winter months. Soft tissue infections are usually preceded by an initial colonization of the skin by group A streptococci, after which the microorganisms are introduced into superficial or deep tissues through disruption of the skin barrier.

Clinical manifestations

Suppurative streptococcal diseases

Pharyngitis

S. pyogenes is the most common bacterial causing pharyngitis in children and teenagers. Main symptoms consist of sore throat, sudden onset of fever and absence of cough. Physical examination findings include cervical lymphadenopathy, pharyngeal swelling, and tonsillar exudate. Palate petechiae and uvular edema are also suggestive of this disease. But, despite these clinical signs and symptoms, it is difficult to distinguish streptococcal pharyngitis from viral pharyngitis. A diagnosis definitive can only be achieved by specific laboratory tests (Ashurst and Edgerley-Gibb, 2021).

A complication of strep throat is the scarlet fever, which is characterized by a bright red rash that affects to most of the body. It is almost always accompanied by a sore throat and high fever. Some of the symptoms produced by the scarlet fever, in addition to the red rash are red lines (Pastia lines), where the folds of skin around the groin, armpits elbows, knees and neck usually become deeper red than the surrounding rash and strawberry tongue, that is often covered with a white coating early in the disease.

Impetigo

The lesion of streptococcal pyoderma begins as a papule that rapidly evolves into a vesicle, surrounded by an area of erythema. Vesicular lesions are evanescent and rarely recognized clinically; they give rise to pustules that gradually enlarge and then break down over a period of 4–6 days to form characteristic thick crusts. Streptococcal impetigo occurs on exposed areas of the body, most often on the lower extremities or in the face. Although regional lymphadenitis may occur, systemic symptoms are usually not present (Stevens and Bryant, 2016).

Erysipela

Erysipela is a skin infection that affects the dermis layer of the skin, but may also extend to the superficial lymph nodes. It is characterized by a well demarcated, raised area of erythema often affecting the lower extremities, with the face being the second most common site affected (Michael and Shaukat, 2021).

All age groups may be affected, but it is more common at the extremes ages (Klotz et al., 2019).

Cellulitis

It is an acute disseminated inflammation of the skin and subcutaneous tissues. Unlike erysipela, the lesion is not raised, the demarcation between affected and unaffected skin is indistinguishable, and the lesions are pinkish rather than salmon red in color. However, the clinical differentiation between these entities is not clear.

Clinical findings include local pain, tenderness, swelling and erythema. The process may spread rapidly to involve large areas of skin. Systemic manifestations include fever, chills, and malaise, and there may be associated with lymphangitis and/or bacteremia (Stevens and Bryant, 2016).

Necrotizing fasciitis

It is defined as a rapidly progressive infection affecting the skin, subcutaneous cellular tissue, superficial fascia and occasionally deep fascia, resulting in tissue necrosis and systemic toxicity (Bueno Rodríguez et al., 1999).

It is usually polymicrobial, but in the majority of cases in which only a single microorganism is isolated, it is produced by *S. pyogenes* (Headley, 2003). Some signs can help differentiate necrotizing fasciitis from cellulitis such as toxic appearance, generalized erythematous rash, high fever, tachypnea and low platelet count (Clark et al., 2000).

Given the characteristics of this disease, early medical treatment is necessary to save the patient. Unlike cellulitis, which can be treated with antibiotics, fasciitis must also be treated aggressively by surgical debridement of the infected tissue.

Streptococcal toxic shock syndrome (STSS)

STSS is one of the complications of invasive streptococcal disease and is defined as the isolation of group A *Streptococcus* from a normally sterile site in the setting of shock and multiorgan failure. It should be suspected and recognized early in order to offer appropriate treatment and support measures (Zavala et al., 2018).

An increased risk of the disease can be observed in patients with human immunodeficiency virus (HIV) infection, cancer, diabetes, lung or heart disease, varicella zoster virus infection, as well as those addicted to injecting drugs and alcoholics.

Non-suppurative streptococcal diseases

Rheumatic fever

Rheumatic fever is a multisystemic immune-mediated inflammatory disease that occurs predominantly in childhood and teenagers and follows infection with *S. pyogenes*. It is characterized by fever, migratory polyarthritides of predominantly large joints, carditis, skin and soft tissue changes (erythema marginatum and subcutaneous nodules) (Carapetis et al., 2005; Lozano et al., 2012).

There is no single diagnostic test for rheumatic fever. The diagnosis is based on clinical criteria and evidence of preceding infection with *S. pyogenes* like (1) positive results of pharyngeal swab cultures or test based on specific nucleic acids; (2) detection of group A antigen in pharyngeal smear, or (3) an elevation of anti-ASLO, anti-DNAase B or antihyaluronidase antibodies (Steer, 2015).

Acute glomerulonephritis

The glomerulonephritis is characterized by acute inflammation of the renal glomeruli with edema, hypertension, hematuria and proteinuria. It is a sequelal of pyoderma and pharyngeal streptococcal infections. Diagnosis is based on clinical manifestations and finding of recent *S. pyogenes* infection (Satoskar et al., 2020).

Laboratory diagnosis

Microscopy

Gram's staining of tissue samples affected by *S. pyogenes* infection is crucial for rapid and preliminary diagnosis and for starting empirical treatment. However, many streptococcal species are part of the normal oropharyngeal microbiota, and the observation of streptococci in such samples has low predictive value (Abbour et al., 2016).

Antigen detection

There are many immunological tests that use antibodies that react with the specific carbohydrates of the bacterial cell wall to identify group A streptococci in pharyngeal swabs directly. Simple rapid antigen detection tests are widely used to diagnose pharyngitis by Streptococci group A at the point of care. The sensitivity in children is approximately 85%, and specificity is high, at approximately 95%. It is not recommended relying on negative tests results without culture confirmation (Cohen et al., 2016).

Culture

Throat culture is the gold standard for the diagnosis of streptococcal pharyngitis and it has a sensitivity from 90% to 95%. Samples should be taken from the posterior oropharynx despite the difficulty of obtaining pharyngeal exudates in the pediatric population (Anjos et al., 2014).

Isolation of *S. pyogenes* from skin infection is not difficult. The scab is lifted and the purulent material and the base of the lesion is cultured. These microorganisms are easily recovered from both tissue and blood cultures from patients with necrotizing fasciitis.

Identification

The *S. pyogenes* colonies measure >0.5 mm in diameter, are white or gray and some have a mucous appearance. The edges are surrounded by a large zone of beta-hemolysis, which is bigger in areas of low oxygen concentration. Streptococci does not produce catalase. In addition, this microorganism is susceptible to bacitracin, the presence of any inhibition halo with a disk containing 0.04 units of bacitracin is diagnostic. Another definitive test for the identification of *S. pyogenes* is the detection of pyrrolidonyl arylamidase (PYR) and the detection of Lancefield's A antigen using commercially available systems (Batista et al., 2006).

Treatment

Penicillin is the antimicrobial of choice for the treatment of *S. pyogenes* infections. However, in penicillin allergic patients, an oral cephalosporin or a macrolide are alternatives treatments. *S. pyogenes* may exhibit macrolide resistance because active efflux (mef genes) or target modification (erm genes), the latter conferring cross resistance to lincosamines and streptogramin B. The combined use of intravenous penicillin with clindamycin is recommended in severe systemic infections (Silva-Costa et al., 2015). Patients with severe penicillin hypersensitivity can be treated with linezolid, vancomycin or daptomycin (Stevens et al., 2014). In patients with severe soft tissue infection, drainage and surgical debridement should be initiated promptly.

Streptococcus agalactiae

Streptococcus agalactiae, also known as group B *Streptococcus* (GBS) was described as a colonizer of the vaginal tract of asymptomatic women. However, its pathogenesis was not described until 1938 when reports of fatal postpartum infection were published. Invasive GBS disease remains an important pathogen in both infants and adults (Raabe and Shane, 2019). The serotypes of GBS are based on the capsular polysaccharide and it has been divided into nine serotypes (Ia, Ib, II, III, IV, V, VI, VII, VIII). The most common serotype causing invasive disease is group V (Edwards and Baker, 2015). GBS can cause septicemia, pneumonia and meningitis in newborns and serious illness in adults.

Epidemiology

Vaginal colonization by *S. agalactiae* represents the most important risk factor for the development of invasive neonatal infections. The rate of GBS colonization in pregnant women in the vagina and/or rectum varies by geographic area, from 6.5% to 36% in Europe, from 10% to 30% in the United States, from 7.1% to 16% in Asia, from 9.1% to 25.3% in the Middle East, and from 11.9% to 31.6% in Africa (Verani et al., 2010).

Because GBS colonization status is intermittent and may be transient during pregnancy, the timing of microorganism detection and specimen collection is important in predicting colonization status at delivery (Hansen et al., 2004). CDC guidelines determine that the best time for detection is late in the third trimester, no more than 5 weeks before delivery (Verani et al., 2010).

Currently, up to 10 serotypes (Ia, Ib and II-IX) based on a capsular polysaccharide rich in sialic acid, which acts as a virulence factor in the persistence and survival of GBS within the host, are recognized (Le Doare and Heath, 2013). Although, colonization rates appear quite similar in different geographical areas, the prevalence and distribution of serotypes is not the same in the different regions of the world (Xia et al., 2015). In Europe and the United States the more prevalent serotypes are Ia, Ib, II, III and V. Serotype III accounts for the majority of cases of late-onset neonatal meningitis (Alhhazmi et al., 2016).

Microbiology

Group B streptococci are Gram-positive cocci that form short chains in clinical specimens and longer chains in culture, that make them indistinguishable from *S. pyogenes* on Gram staining. *S. agalactiae* colonies have a buttery appearance and a narrow zone of beta-hemolysis.

The polysaccharide capsule is the most important virulence factor of GBS, which interferes with phagocytosis until the patient generates specific antibodies. In the absence of maternal antibodies, the newborn is at risk of infection. The genital colonization by group B streptococci is associated with an increased risk of preterm partum, and infants are at increased risk for the disease.

Pathogenesis

Many of the virulence determinants of GBS contribute to neonatal disease, based on adherence to epithelial surfaces, penetration of host cellular barriers, evasion of immune clearance mechanisms, and inflammatory activation (Doran and Nizet, 2004).

The main virulence factor is the polysaccharide capsule. The antibodies developed against the capsule antigen are protective, and in the absence of these, the neonate is at increased risk for acquiring the infection. The fact that GBS colonizes the genital area is associated with an increased risk of preterm delivery, and newborns are at increased risk for the disease (Murray et al., 2013).

Clinical manifestations

Early-onset neonatal disease

Early-onset disease is mainly associated with bacteremia, pneumonia or meningitis. Lung involvement is seen in the majority of neonates, but meningeal involvement may be apparently undetectable, so examination of cerebrospinal fluid would be necessary in all infected neonates.

A few years ago the mortality rate was quite high, but thanks to early diagnosis and improved treatment it has decreased to less than 5%.

Late-onset neonatal disease

It has an exogenous origin and develops between the first week and 3 months of life. It is usually associated with bacteremia and meningitis, and although it has a low mortality rate, 25–50% of children with meningitis develop neurological complications.

Infections in pregnant women

During gestation or even immediately after delivery, infection often leads to postpartum endometritis, wound infection and genitourinary tract infections. The outcome is usually favorable in pregnant women who receive appropriate treatment.

Infections in men and non-pregnant women

The most frequent forms of infection are bacteremia, pneumonia, bone, skin and soft tissue infections. Affecting men and women of advanced age and suffering from other pathologies such as diabetes mellitus, cancer, and/or immunosuppression. Mortality is higher in this population (Murray et al., 2013).

Diagnosis

As mentioned above, the timing of specimen collection is very important for the detection of GBS. A swab should be taken from both the distal vagina and rectum, as it significantly increases the recovery of this microorganism, between the 35th and 37th week of pregnancy (Verani et al., 2010).

Swabs can be seeded on blood agar, colistin-nalidixic acid agar (CNA), Granada agar or chromogenic agar. Plates are incubated at 35–37 °C and should be examined for GBS-like colonies at 24 and 48 h. Orange colony growth should be observed on Granada agar. Colonies growing on other media can be confirmed by additional tests such as latex agglutination or the CAMP test (Nickmans et al., 2012).

To distinguish GBS from other beta-hemolytic streptococcal species, detection of the reddish polyene pigment grenadaene, which is linked to the expression of GBS β -hemolysin, is used (Spellerberg et al., 2000) (Fig. 1). As no other species produces this pigment, it can be used as a simple and specific method for one-step detection of SGB. It is carried out on Granada agar media, already mentioned above (Rosa-Fraile et al., 2014). But not all strains produce pigment, as 2–5% of human colonizing GBS isolates are not hemolytic and do not produce pigment (Tazi et al., 2009).

Fig. 1 *S. agalactiae* in Granada agar.

In addition to identification by biochemical tests such as CAMP, or the pyrrolidonyl arylamidase (PYR) test, it can be identified by MALDI-TOF MS mass spectrometry because it is fast and accurate (Lartigue et al., 2009).

Regarding to molecular diagnosis, in recent years several specific PCR assays have been developed for the detection of GBS colonization, employing different genetic targets. Most are currently incorporated in automated molecular platforms such as the BD MAX system (Becton, Dickinson), SmartCycler and Xpert (Cepheid). It can be performed directly with the clinical swab. The main advantage of PCR is the short time to report results regarding GBS colonization status at delivery. Despite being a rapid and sensitive technique, it is recommended to perform culture (Verani et al., 2010).

Treatment

SGB is considered susceptible to penicillin, although reduced sensitivity has been detected in some isolates, which is believed to be secondary to reduced expression of the PBP2 protein (Seki et al., 2015). Thus, penicillin G remains the treatment for invasive disease. GBS is sensitive to beta-lactams such as ampicillin, first, second and third generation cephalosporins and carbapenems. In penicillin-allergic patients, alternative treatment includes clindamycin, erythromycin, fluoroquinolones and vancomycin. However, increased resistance has been detected in these antibiotics and they should only be used if the patient is allergic to penicillins and their susceptibility has been proven (Piccinelli et al., 2015).

The duration of treatment is usually 10 days in infections such as bacteremia, pneumonia, pyelonephritis and skin and soft tissue infections. For meningitis, a longer duration, about 2 weeks, is recommended (Edwards and Baker, 2015).

In newborns with early-onset disease, empirical treatment consists of ampicillin in combination with an aminoglycoside. A 10-day therapy is recommended for uncomplicated bacteremia and 14 days for uncomplicated meningitis, whereas a complicated infection may require a longer duration of treatment (Kimberlin et al., 2015).

Anginosus group

Among the remaining β -hemolytic *Streptococci*, the *Streptococcus anginosus* group is the most important and includes *S. anginosus*, *S. constellatus* and *S. intermedius* among others. It is usually associated with suppurative infections and abscesses. It can see as small colonies, which may be observed with alpha, beta or without hemolysis and could belong to Lancefield groups A, C, G or F, and they usually have a characteristic caramel odor. They colonize human mucous membranes, oral, genital and gastrointestinal (Whiley et al., 1992).

Viridans group

This group includes several species, most of which have similar characteristics, they form part of the mucous membranes of mammals, have low virulence, are in the form of small colonies (<0.5 mm) and most are alphahemolytic (from which comes its name viridans, green).

This group includes *Streptococci* belonging to the mitis group (except *S. pneumoniae*), *anginosus*, *salivarius* and *mutans* (Alam et al., 1999).

Bovis group

This group of *Streptococci* belongs to Lancefield's group D and grows in the presence of bile-esculin, they are related to isolations in patients with endocarditis or any underlying disease affecting the colon. The most important species of this group is *S. gallolyticus* which have two subspecies, *gallolyticus* and *macedonicus* is isolated in bovine mastitis and also in cases of human endocarditis associated with colon neoplasia (Schlegel et al., 2003).

Enterococcus

Introduction

The genus *Enterococcus* comprises a ubiquitous group of Gram-positive bacteria that have become highly relevant to human health because of their role as major causative agents of health care-associated infections. They are able to survive in difficult conditions, and are therefore well adapted to the hospital environment. They show intrinsic resistance to several common antibiotics, including some beta-lactams such as cephalosporins, aminoglycosides, trimethoprim-sulfamethoxazole and clindamycin. This fact supposes a prolonged hospitalization time, increases both the cost of treatment and increases the risk of treatment failure and death (García-Solache and Rice, 2019).

This genus consists of several species but most of them are caused by *Enterococcus faecalis* and *Enterococcus faecium*, which can easily acquire resistance to other antibiotics, such as high-level ampicillin resistance or resistance to glycopeptides such as vancomycin, either by mutation or by horizontal transfer of genetic elements that confer resistance determinants.

These microorganisms are common residents of the gastrointestinal tract of almost all terrestrial animals, including humans, and the main infections that they produce include urinary tract infections, bacteremia, intraabdominal infections and endocarditis (Selleck et al., 2019).

Epidemiology

Enterococci have been isolated from soil, surface water and seawater; in plants; in fermenting food products, and from the intestinal microbiota of vertebrates and invertebrates (Švec et al., 2005).

The most common species isolated in the human gastrointestinal tract are *E. faecium* and *E. faecalis*, being *E. faecium* isolated from production animals and *E. casseliflavus* from plant sources (Klein, 2003). The number of *E. faecalis* in human feces varies from 10^5 to 10^7 per gram, and of *E. faecium* from 10^4 to 10^5 per gram (Franz et al., 1999).

Epidemiological studies have reported that *E. faecalis* and *E. faecium* species are regularly isolated from food such as cheese, fish, sausages and pork meat (Foulquié Moreno et al., 2006).

The distribution of *Enterococcus* species varies throughout Europe. In countries such as Spain and the United Kingdom, the most commonly isolated species are *E. faecalis* and *E. faecium*, both from clinical and environmental sources (Kühn et al., 2003).

Some risk factors that are associated with enterococcal infections include the use of urinary or intravascular catheters, prolonged hospitalization and the use of broad-spectrum antibiotics (Murray et al., 2013).

Regarding to the resistance of these microorganisms, they can acquire some resistance genes. Acquired resistance to beta-lactams is due to hyperproduction or alterations in PBP5, while the production of betalactamase enzymes is rare in these microorganisms. Most *E. faecium* isolates are resistant to ampicillin. However, resistance of *E. faecalis* to this antimicrobial is rare. Acquired resistance to glycopeptides is due to the acquisition of resistance operons called VanA, vanB, vanD, VanE. In Spain, resistance to vancomycin and teicoplanin is uncommon and generally below 5% (Cercenado, 2016).

Microbiology

Enterococcus spp. are Gram-positive, catalase negative, non-spore-forming bacteria, which can appear either as single cocci or as pairs, chains or clusters (Woodford, 1998). They are chemoorganotrophic facultative anaerobes with homofermentative metabolism, with lactic acid as the predominant end product of carbohydrate fermentation (Švec and Franz, 2014). They are identified with a low G + C content of 34–45% (Zhong et al., 2017).

The term *Enterococcus* was first described by Thiercelin in 1899, when he described intestinal commensal bacteria with the ability to become pathogenic (Bouvet and Couvry, 1994). Based on a 1970 study, proposed that they should be placed in the genus *Enterococcus* (Scheleifer and Kilpper-Bälz, 1984). This genus consists of 58 described species. It belongs to the family *Enterococcaceae* which is in the order *Lactobacillales*, class *Bacilli* in the phylum *Firmicutes*.

Most *Enterococci* are oxidase and catalase negative, salt tolerant, resistant to 40% bile, and esculin hydrolytic. *E. faecalis* and *E. faecium* will grow in a wide pH range (4.6–9.9). *E. faecalis* can grow in 6.5% NaCl and has a cation homeostasis that is believed to contribute to its resistance to Ph, salt, metals and desiccation. They can growth between 10 and 45 °C, with optimal growth for most species between 35 and 37 °C. Both microorganisms can survive heating 60 °C for 30 min, which makes *Enterococcus* species different from other closely related genera such as *Streptococcus* (Foulquié Moreno et al., 2006).

When it is cultured on horse blood agar, *Enterococci* can show both alpha and beta-hemolysis and no hemolysis. They form 1 to 2 mm colonies with a wet appearance. Given their metabolic capabilities, different selective culture media have been developed for the isolation of *Enterococci*, containing bile salts, antibiotics, esculin salts or tetrazolium. The most clinically relevant species grow well on these media. Clinical tests for identification of *Enterococci* include the catalase production test, the pyrrolidonyl arylamidase/pyrrolidonyl aminopeptidase (PYP) test and the bile esculin hydrolysis test (England, 2014).

Pathogenesis

The virulence of *Enterococcus* species is mediated by several factors: ability to colonize the gastrointestinal tract, which is the normal habitat; ability to bind to a variety of extracellular matrix proteins, including thrombospondin, lactoferrin and vitronectin; and ability to adhere to urinary tract epithelium, oral cavity epithelium, and human embryonic kidney cells.

Colonization of the gastrointestinal tract is directly related to the risk of infection (Taur et al., 2012), which occurs when the microorganism overwhelms host defenses, replicates at high rates that exceed clearance, and when pathological changes result from direct toxin activity (Garsin et al., 2014).

There are several proteins described as virulence factors of pathogenic *Enterococci*. Microbial surface components that recognize adhesive matrix molecules are surface elements that help *Enterococci* adhere to host tissues.

Pilin gene clusters (PGCs) are present in both *E. faecalis* and *E. faecium* and encode surface proteins, called pili that can function as adhesins. The PGC ebp (endocarditis- and biofilm-associated pilus) in *E. faecalis* is associated with initial adhesion and biofilm formation and has been implicated in the pathogenesis of endocarditis and urinary tract infections (Nallapareddy et al., 2006).

Another protein involved in the virulence of *E. faecalis* is the cytolysin (Cyl), encoded by the cylL L and cylL S genes. It can damage host cells and promotes infection (Haas et al., 2002).

The gelatinase (GelE) of *E. faecalis*, is a matrix metalloproteinase that hydrolyzes gelatin, collagen, and other proteins. It is implicated in the development of endocarditis. The cell wall associated enterococcal surface protein (Esp) contributes to cell adhesion in both microorganisms and it is implicated in urethral colonization and endocarditis and promotes biofilm formation (Thurlow et al., 2010).

Genes encoding several of these virulence factors are often placed on PAIs or mobile elements, which facilitates their spread between isolates. PAIs are large elements that can be acquired by horizontal transfer and confer virulence to bacterial pathogens (Gal-Mor and Finlay, 2006).

In addition to secreted proteins, it has been shown that *E. faecalis* and *E. faecium* can produce toxic oxygen metabolites that can cause cellular damage.

Clinical manifestations

Bacteremia

Enterococcal bloodstream infections are associated with a high mortality rate and are due to the result of translocation of *Enterococci* from the intestine into the bloodstream (Billington et al., 2014).

Risk factors associated with enterococcal bacteremia include severity of illness, patient age, and use of third-generation cephalosporins (Stroud et al., 1996). Common sources for community-acquired bacteremia are the gastrointestinal tract and urinary tract (Arias and Murray, 2015). They are usually acquired from intravascular or urinary catheters, but they have also been associated with intraabdominal, burn wound, pelvic, biliary and bone sources.

Bacteremia caused by glycopeptide-resistant *Enterococci* is associated with a 2.5 fold increase in mortality compared to vancomycin-sensitive *Enterococci* bacteremia (Salgado, 2008).

Urinary tract infection

Enterococci are one of the most commonly isolated gram-positive bacteria from catheter-associated urinary tract infections, being the majority of them *E. faecalis* isolates (Weiner et al., 2016).

Some studies showed a potential role of plasmid-encoded aggregation substance in enterococci adhesion to renal epithelial cells. Several recent studies have identified a pilus in *E. faecalis*, and have shown that Ebp pili are important for adhesion to urinary epithelium and urinary catheters through binding of fibrinogen released into the bladder during catheterization (Tomita and Ike, 2004).

Urinary tract infections tend to be more common in men and are associated with recurrent urinary tract infections, previous antibiotic treatment, indwelling catheters, instrumentation and abnormalities of the gastrointestinal tract (Arias and Murray, 2015).

Endocarditis

Infective endocarditis caused by *Enterococci* represents one of the most therapeutically challenging clinical manifestations. *Enterococci* cause 10–20% of all cases of infective endocarditis and *E. faecalis* cause the majority of cases (Giannitsioti et al., 2007).

One of the most important virulence factors causing this infection is the adhesion to host tissues by cell surface adhesins. In *E. faecalis*, aggregating substance (AS) represents a class of large surface proteins involved in mediating cell-to-cell adhesion (Clewett et al., 2014). These proteins also appear to be key players in both cardiac tissue attachment and biofilm development during infective endocarditis. Three proteins are related, Asa1, Asc10 and Asp, and they help in cell-to-cell adhesion and also contribute to the exopolymeric matrix that accumulates within the biofilm (Chuang-Smith et al., 2010).

As in bacteremia production, the pili encoded by the Ebp group in *E. faecalis* are important for both adherence and biofilm formation. Other important virulence factors in *E. faecalis* IE include the metalloprotease GelE, the collagen-binding adhesin Ace, the fibronectin-binding protein EfbA, cytolysin, and the PTS permease BepA.

In *E. faecium* specific virulence factors and the role they play in infective endocarditis are unknown. However, the enterococcal surface protein Esp and the collagen-binding protein Acn have been shown to be important for the pathogenesis of this species (Heikens et al., 2011).

As for endocarditis caused by vancomycin-resistant strains of *E. faecalis*, these are associated with central venous tract, liver transplantation and mitral valve infections, whereas endocarditis caused by vancomycin-resistant *E. faecium* is usually associated with tricuspid valve infection (Forrest et al., 2011).

Enterococcal endocarditis usually presents as a subacute course, with the most common clinical manifestations being the presence of a murmur, fever, weight loss, malaise, and generalized aches and pains (Arias and Murray, 2015).

Intra-abdominal and pelvic infections

Since *Enterococci* are part of the microbiota of the gastrointestinal tract, they are commonly isolated with pelvic and intra-abdominal infections, usually along with other microorganisms. Treatment of intra-abdominal enterococcal infections is considered acceptable in immunocompromised patients and the critically ill associated with abscesses, wounds or peritonitis in patients with damaged heart valves to prevent bacteremia or endocarditis (Arias and Murray, 2015; Harbarth and Uckay, 2004).

Skin and skin structure infections

These microorganisms colonize the skin and may be associated with infections of the skin and skin structures. They are usually isolated in polymicrobial infections and their pathogenic role is unclear. They can be isolated from decubitus ulcers and diabetic foot ulcers, and sometimes in osteomyelitis, septic arthritis and soft tissue abscesses (Agudelo Higuera and Huycke, 2014).

Diagnosis

Enterococci can grow readily on non-selective media such as blood agar and chocolate agar. On Gram stained these microorganisms can be seen as cocci in pairs or forming chains and can be easily differentiated by simple biochemical reactions. *Enterococci* are optoquine resistant, while *S. pneumoniae* is susceptible, do not dissolve when exposed to bile and produce L-pyrrolidonyl-arylamidase (PYR). Catalase-negative and PYR-positive cocci that are arranged in pairs or short chains are identified as *Enterococci*.

Identification of *Enterococci* to species level has clinical relevance due to antibiotic resistance profiles of the different pathogenic *Enterococci*. New molecular techniques are also useful for epidemiology and surveillance and in the diagnosis of difficult cases. Molecular-based methods have the advantages of increased diagnostic accuracy, provide information of antimicrobial resistance, and reduce time and costs compared to traditional culture and phenotypic testing.

New systems for the classification and identification of these microorganisms include matrix-assisted laser desorption ionization- time-of-flight mass spectrometry (MALDI-TOF MS), nucleic acid amplification testing (NAAT), in situ hybridization, and multilocus sequence typing (MLST).

Clinical use of MALDI-TOF MS based methods allows rapid identification of *Enterococci* directly from blood culture bottles, potentially reducing the time to initiation of antimicrobial treatment. This technique has a high sensitivity, being able to identify about 94% of isolates to species level, including differentiation between closely related species (Stepień-Pyśniak et al., 2017). In addition, it could be quite useful for antibiotic resistance profiling, for detecting the presence of van genes, although it is not yet used in clinical practice (Singhal et al., 2015; Bizzini and Greub, 2010).

NAAT methods are based on PCR amplification and subsequent sequencing or array/hybridization or real-time PCR amplification of genes that are useful for identification of organisms to genus or species level and important for detecting antimicrobial resistance genes (Ljungström et al., 2015).

Sequencing of the 16S rRNA gene is commonly used to identify bacterial species and allows differentiation of enterococci to the species level. Multiplex real-time PCR allows testing for more than one gene, allowing determination of both species and antibiotic resistance genes at the same time (Bosshard et al., 2004).

Hybridization allows rapid detection of the presence of *Enterococci* in blood culture bottles. These tests enable differentiation of *E. faecalis*, *E. faecium* and other less common *Enterococci* species (Deck et al., 2014).

Another technique used in strain identification is multilocus sequence typing (MLST) which is used to study molecular epidemiology and to study outbreaks, which is more reproducible and less laborious than pulsed-field electrophoresis (PFGE) analysis (Ruiz-Garbajosa et al., 2006).

Treatment

Antimicrobial treatment of enterococcal infections is complicated. Treatment of severe infections has traditionally consisted of the synergistic combination of an aminoglycoside and an antibiotic able to inhibit cell wall synthesis.

The genus *Enterococcus* is characterized by reduced susceptibility to many infectious agents, active against other Gram-positive microorganisms. Enterococci are intrinsically resistant to almost all cephalosporins (with possible exceptions such as ceftaroline and ceftobiprole), antistaphylococcal penicillins, and aztreonam (Murray, 1990).

Enterococci are usually susceptible to vancomycin, although in recent years resistance to this antimicrobial is increasing, which we will discuss in this section. The emergence of vancomycin-resistant *Enterococcus* as an important nosocomial pathogen is due to its propensity for colonization of the gastrointestinal tract, persistence in hospital settings, genome plasticity, mobile genetic elements and increased mortality. In addition, they are resistant to clindamycin, trimethoprim-sulfamethoxazole and clinically achievable concentrations of aminoglycosides (Florescu et al., 2008).

New antimicrobials such as linezolid, tedizolid, daptomycin, telavancin, and oritavancin are active against *Enterococci*. In the clinical setting, the treatment of choice remains ampicillin in susceptible strains and patients who can tolerate this drug (de Lastours et al., 2017).

The mechanism of resistance of *Enterococci* against β -lactams, is attributed to the expression of a low-affinity penicillin-binding protein (PBP), PBP4 in *E. faecalis* and PBP5 in *E. faecium* (Duez et al., 2001). Therefore, most *Enterococci* are tolerant to the bactericidal activity of β -lactams, making them bacteriostatic. Another mechanism by which resistance to beta-lactams can occur is the production of β -lactamases, but this is not very common in *Enterococci*, although it can lead to a high level of resistance to ampicillin by hydrolyzing β -lactams before they reach their target in the cell wall. To treat severe infections such as endocarditis or meningitis, a synergistic bactericidal combination of a β -lactam with an aminoglycoside can be used. Treatment of endocarditis is currently based on combinations of ampicillin, which is active against *E. faecalis* and ceftriaxone, although the mechanism of this synergism is not clear, it has been postulated that the combination of the two antibiotics inhibits all PBPs of *E. faecalis* more effectively than either antibiotic alone (Pericas et al., 2014).

Acquired antimicrobial resistance

β -lactams resistance

As described above, *Enterococci* are intrinsically resistant to most β -lactams, being susceptible only to a small number of penicillins such as ampicillin, penicillin and piperacillin (Rice and Murray, 1995). Resistance to these penicillins can be produced through two mechanisms, as summarized above, the first and less important, the production of β -lactamases; this β -lactamase has been

identified as identical to that produce by *S. aureus* in some cases within genetic regions identical to that of the Tn 551 transposon (Rice and Marshall, 1992). The other, more important mechanism, also mentioned above is high-level penicillin resistance in *E. faecium* due to the expression of low-affinity PBP5 (Rice et al., 2004). In addition in these species a mutation occurs in the *pbp5* gene leading to amino acid substitutions near the active site of the enzyme (Rice et al., 2004; Rybkine et al., 1998). Epidemiological sequencing data suggest that strains with a high level of ampicillin resistance belong to relatively few lineages that have been spreading, mainly in hospitals, causing infections and colonization of patients exposed to a variety of antibiotics. In the case of *E. faecalis* higher level penicillin resistance is usually rarer than in *E. faecium*. It is due to a higher expression of low affinity PBP4. The fact that deletion of PBP4 or PBP5 results in susceptibility to β -lactams of *E. faecalis* and *E. faecium*, respectively, indicates that these proteins are necessary for resistance (Rice et al., 2018). But other proteins necessary for resistance expression have been found. In *E. faecalis*, the CroRS regulatory locus is necessary for cephalosporin resistance and the presence of genes for two of the three class A PBPs of this microorganism (*ponA* and *pbpZ*) are also necessary for cephalosporin resistance (Kellogg et al., 2017). Deletion of the equivalent class A PBPs in *E. faecium* also increases susceptibility to cephalosporins (Arbeloa et al., 2004).

Glycopeptide resistance

Vancomycin has been an active antibiotic against *E. faecalis* and *E. faecium* for almost three decades after its clinical introduction. In the early 1980s, resistant strains began to emerge, expressing high-level inducible resistance to vancomycin and the more recently introduce antibiotic teicoplanin (Shales et al., 1989). This resistance was attributed to the acquisition by these microorganisms of operons that altered the nature of the peptidoglycan precursors, producing a substitution of a D-lactate for the terminal D-alanine in the UDP-MurNac pentapeptide (Arthur and Courvalin, 1993). The mechanism of action of vancomycin is due to binding to the D-terminal alanine of the cell wall precursor, preventing access to PBPs. Since this antibiotic binds to D-lactate-terminating pentapeptide stalks with much lower affinity than to D-alanine-terminating ones, it is not an effective inhibitor of cell wall synthesis in these strains.

The first glycopeptide resistance operon to be described was the *vanA* operon, and this remains the most common operon in the clinical setting. In addition, other phenotypic variants of acquired glycopeptide resistance have been described in *Enterococci* (*VanB*, *VanD*, *VanE*, *VanG*, *VanL*, *VanM* and *VanN*), with one type of intrinsic resistance (*VanC*) that is unique to *E. gallinarum* and *E. casseliflavus* (Reid et al., 2001). *VanA* is responsible for the majority of human cases of VRE worldwide, and is mainly carried by *E. faecium*. These operons are divided into two groups, those that replace the D-alanine terminus with a D-lactate (*VanA*, *VanB*, *VanD* and *VanM*) and those that replace the terminus with a D-serine (*VanC*, *VanE*, *VanG*, *VanL* and *VanN*) (Sassi et al., 2018). Operons encoding proteins that result in precursors ending in D-serine confer lower levels of resistance to vancomycin but remain susceptible to teicoplanin. In contrast, operons terminating in D-lactate confer resistance to vancomycin and teicoplanin, although the *vanB* operon is not induced by the presence of teicoplanin, so strains in which the induction mechanism is intact.

Aminoglycoside resistance

Enterococci are intrinsically resistant to clinically achievable concentrations of aminoglycosides. They are used in the treatment of enterococcal endocarditis in combination with cell wall-active antimicrobials to achieve bactericidal synergism.

Some strains of *Enterococcus* spp. which have expressed high levels of resistance to these antibiotics with very high MICs for gentamicin and streptomycin have emerged, which is due to the expression of aminoglycoside-modifying enzymes and negates the synergistic benefit of these combinations. The gene encoding the most common enzyme conferring resistance to gentamicin is *aac-6'-Ie-aph-2*. Another enzyme that has been associated with lower gentamicin MICs is phosphotransferase *APH(2'')-1c*. In *E. faecium* intrinsic resistance to kanamycin and tobramycin is due to chromosomally encoded *AAC(6')-II*.

Fluoroquinolones resistance

Fluoroquinolones such as ciprofloxacin and levofloxacin are only used in the treatment of urinary tract infections due to susceptible strains of *Enterococci*. Highly resistant strains contain mutations in *gyrA* and *parC* (El Amin et al., 1999).

Linezolid resistance

Linezolid is an antimicrobial active against *E. faecalis* and *E. faecium*. Resistance to linezolid is rare, but has been described in the literature and is associated with duration of pretreatment with linezolid (Vega and Dowzicky, 2017). Resistance to linezolid may be due to two mechanisms, a decrease in binding due to mutations in the 23S ribosomal RNA or to the acquisition of a *cfr* gene (resistance to chloramphenicol-florfenicol resistance) through horizontal transmission, which causes methylation of 23S ribosomal RNA. This enzyme confers resistance to a wide variety of antimicrobial classes, including phenicols, lincosamides, oxazolidinones and streptogramin A (Vester, 2018).

Linezolid is effective in the treatment of vancomycin-resistant *E. faecium* bacteremia and is recommended as a first-line treatment option for infective endocarditis due to ampicillin- and vancomycin-resistant *Enterococci* (Scheetz et al., 2008).

Linezolid has good central nervous system (CNS) penetration and has been used successfully as monotherapy for vancomycin-resistant *Enterococci* CNS infections (Knoll et al., 2013).

A new oral and parenteral oxazolidinone called tedizolid with a broad spectrum of bacteriostatic activity against resistant gram positive bacteria has emerged. Tedizolid has a fourfold lower MIC against vancomycin-resistant *Enterococci* compared to linezolid. In addition, it is active against linezolid-resistant strains carrying the *cfr* mutation (Rybak et al., 2014).

Daptomycin resistance

Daptomycin is an antibiotic with dependent bactericidal activity used against some resistant Gram positive microorganisms, including *E. faecalis* and *E. faecium* vancomycin-resistant. Some recent studies have compared daptomycin with linezolid used for the treatment of vancomycin-resistant enterococcus bacteremia and found higher mortality in patients treated with daptomycin. But these studies are limited by several factors, so linezolid and daptomycin should still be used as first-line options for the treatment of VRE bacteremia, although high doses (8–12 mg/kg) should be considered for daptomycin (Chuang et al., 2014).

Due to therapeutic failures and the development of resistance during the use of daptomycin monotherapy for the treatment of enterococcal endocarditis, the possibility of combination therapies and the use of high-dose daptomycin has been explored (Reyes and Zervos, 2013). Resistance to daptomycin is associated with longer durations of therapy and is a function of genetic mutations in genes responsible for biogenesis, permeability, and resistance potential (Arias and Murray, 2015).

Daptomycin monotherapy is not recommended for CNS infections due to its poor penetration with inflamed meninges (Knoll et al., 2013).

Some in vitro studies have shown synergy for combinations of daptomycin with beta-lactams in VRE, including new generation cephalosporins. This combination increases the bactericidal activity of daptomycin and reduces resistance formation (Werth et al., 2015).

Lipoglycopeptides

Telavancin and dalbavancin possess concentration-dependent bactericidal activity against several resistant Gram positive bacteria, including VRE (Zhanel et al., 2010).

Oritavancin has the broadest spectrum of lipoglycopeptides that have bactericidal activity against nearly all resistant gram positive bacteria, including both VRE-expressing VanA and VanB. It represents a promising option for the treatment of VRE infections of the skin and skin structure and possibly bacteremia or even endocarditis, when administered with gentamicin for synergy (Lefort et al., 2000).

Tigecycline

Tigecycline is a glycylcine, which has activity against Gram positive and negative microorganism resistant to tetracycline, including VRE faecalis and faecium. Resistance to tigecycline has not yet been reported in VRE (Meagher et al., 2005).

Tigecycline has been used successfully together with daptomycin for the treatment of VRE infective endocarditis, but should not be used in the treatment of VRE bacteremia due to its high volume of distribution with low serum levels (Jenkins, 2007).

It achieves high penetration into the peritoneal space and has a broad spectrum of activity, which is why it can be used in the treatment of polymicrobial intra-abdominal infection associated with VRE (Scheetz et al., 2006).

Genus *Neisseria*

The genus *Neisseria* is a group of Gram-negative bacteria, and the different species that make it up appear generally (although with some exceptions) in the form of diplococci, with flattened adjacent walls (Tønjum, 2005).

The genus owes its name to the German microbiologist Albert Neisser, who was the first to describe the species *Neisseria gonorrhoeae*. Although 15 species are listed in the latest edition of the Bergey's manual (Bergey's Manual of Systematic Bacteriology) (Tønjum, 2005), a good number of new species have been proposed whose taxonomic position is not yet resolved (Diallo et al., 2019).

Of all the species described, only two, *Neisseria meningitidis* and *Neisseria gonorrhoeae* are pathogenic for humans, while the rest are usually found as commensals of humans and animals, on mucosal surfaces, such as the epithelium of both the nasopharynx or the genital (Rotman and Seifert, 2014).

Although conventionally the species of the genus have been distinguished based on their phenotypic properties, such as the use of carbohydrates and enzymatic tests, which generally give satisfactory results for the identification of meningococcus (*N. meningitidis*) and gonococcus (*N. gonorrhoeae*), misclassification using these methods are not uncommon (Dossett et al., 1985), so it is increasingly common to use molecular methods for identification purposes (Bennett et al., 2012) and phenotypic differences are less and less used in the determination of species, being replaced by a genetic approach.

Neisseria meningitidis

Neisseria meningitidis, also known as meningococcus, is one of two pathogenic species in the genus. Its history begins in 1887, when Weichselbaum first identified the bacteria in cerebrospinal fluid from a patient with meningitis, although its association with the production of epidemics of cerebrospinal meningitis had already occurred in 1805 in Geneva (Switzerland), in 1806 in Massachusetts and in the early 1900s in the African meningitis belt (Rouphael and Stephens, 2012).

To be more precise, *N. meningitidis* can be considered as an accidental pathogen, with the bacterium only rarely causing life-threatening disease. Its only known natural habitat is the mucosa of the human nasopharynx. This phenomenon of colonization of the upper respiratory tract is known as “carriage,” and represents a successful commensal relationship between the host and the bacteria (Caugant and Maiden, 2009), without the host showing any pathology. However, the development of the disease represents in some way a dysfunctional failure in that commensal balance between both protagonists.

Invasive meningococcal disease

The bacteria *N. meningitidis* is the etiological agent associated with Invasive Meningococcal Disease (IMD), a devastating disease that remains a public health concern because of its rapid onset and significant risk of death and long-term disability (Wang et al., 2018). Even with proper therapy, 5–10% of patients die 24–48 h after the onset of symptoms (Olbrich et al., 2018). Additionally severe permanent sequelae in those surviving to septicemia include severe skin necrosis and scarring requiring skin grafts and amputation of limbs, with long-term sequelae in 10–20% of survivors (Olbrich et al., 2018).

Meningococcus usually causes meningitis and sepsis in susceptible individuals. However, the presentation of unusual clinical forms or symptoms that have not been classically associated with meningococcal infection is becoming more and more frequent (Stinson et al., 2020). The unusual clinical presentations of meningococcal disease include: abdominal presentation (abdominal pain, gastroenteritis, diarrhea and peritonitis) (Vienne et al., 2003), complicated forms of meningitis (Toubiana et al., 2013), cardiac manifestations and arthritis (Vienne et al., 2003), meningococcal pneumonia (Vossen et al., 2016). Strains belonging to the cc11 either from serogroup W or C appear overrepresented in most of these unusual clinical presentations except in pneumonia, where serogroup Y cc23 are the most prevalent (Campbell et al., 2019).

Meningococcal carriage (reservoir and transmission)

The only known ecological niche of *N. meningitidis* is the human nasopharynx. The acquisition of the bacteria requires a previous person-to-person transmission through direct contact or contact with drops from the respiratory tract of an infected individual to another susceptible (Caugant and Maiden, 2009). The phenomenon by which an individual is infected in the nasopharyngeal mucosa without developing any symptoms or signs of disease is known as carriage.

Carriage rates are very variable among human populations, and it is associated with the age. Global carriage rates in Europe and the United States have been estimated to range from 10% to 35% in young adults (Caugant and Maiden, 2009) and it is very likely that throughout his life an individual will be a nasopharyngeal carrier at least once in his life.

Age has been shown to be a risk factor for being a carrier of meningococcus, so that in studies carried out in Europe and the United States, the highest rates of carriage are observed in the group of adolescents around 20 years of age, while that carriage is very low in the first years of life, then gradually increasing until adolescence, later decreasing until being around 10% in older ages (Christensen et al., 2010). One of the factors that explain the greater prevalence of bacteria in the group between 17 and 24 years old is more and closeness social contacts in this group of age (MacLennan et al., 2006).

In contrast to isolates from IMD patients, the greater proportion of isolates from asymptomatic carriers are noncapsulated, with a greater presence of unusual serogroups found in IMD cases (Glitza et al., 2008).

Obtaining in-depth knowledge of the transmission dynamics of *N. meningitidis* strains is essential to be able to understand the dynamics of the disease itself, as well as for the selection of vaccination-based strategies (Cartwright et al., 1991). For this purpose, the molecular characterization of the strains has allowed a great qualitative leap in the understanding of these mechanisms (Caugant and Maiden, 2009).

Detection of the presence of the microorganism in clinical samples: Microbiological diagnosis

Early signs and symptoms are usually unspecific, with a range of signs and symptoms that may or may not appear at different times of the disease (Vázquez et al., 2016). Although meningitis and sepsis are the two most frequent symptoms, other presentations may also be observed (e.g., arthritis and pericarditis), and different guidelines recognize different clinical criteria.

Microbiological methods are used to confirm the case. Meningococci are Gram-negative diplococci and can be found extracellularly or intracellularly in peripheral mononuclear leukocytes. Although the Gram stain can be used as a first approximation in the confirmation of a case using CSF samples or blood films, the probability of visualizing a meningococcus in the staining depends

largely on the bacterial load, and the previous administration of antibiotic prior taking the sample slightly reduces the chances of success (Tunkel et al., 2004). Although it is a widely used method due to its low cost and speed of implementation, its low sensitivity and a specificity that largely depends on the operator, does not allow it to be considered the “gold standard method.”

Several rapid diagnostic tests based in antisera directed against the capsular polysaccharide have been used (Vázquez et al., 2016), including counterimmunoelectrophoresis, coagglutination, and latex agglutination. The sensitivity for *N. meningitidis* range between 50% and 93% (Tunkel et al., 2004), being particularly low in clinical samples, so a negative result cannot rule out the presence of a specific meningial pathogen, and false positive results have been also described. For that reasons those test are not usually included in guide lines for meningococcal diagnostic. However, latex agglutination has swon very effective in identifying capsular groups A, B, C, W and Y from culture (Vázquez et al., 2016).

CSF and blood culture are valuable for detection of the causative organism and establish susceptibility patterns. Blood culture is particularly useful if CSF cultures are negative or unavailable, e.g., when lumbar puncture is contraindicated. Growth is optimal at 35–37 °C in ~5% CO₂, on blood agar or chocolate agar plates (Vázquez et al., 2016; Olcen and Fredlund, 2001). The timing of specimen collection is crucial for successful processing of *N. meningitidis* culture and also false-negative results may appear from early antibiotic treatment and incorrect handling or culturing of samples (Olcen and Fredlund, 2001). Carbohydrate utilization tests are used to validate the presence of *N. meningitidis* further. Matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDITOF) has also been described for routine identification but some improvement of meningococcal identification might be required (Cunningham et al., 2014).

Finally, molecular methods such as the polymerase chain reaction (PCR), real-time PCR (rtPCR), qualitative or quantitative PCR (qPCR), and loop-mediated isothermal amplification assays (LAMP), have been developed and used in the diagnosis and characterization of *N. meningitidis*, with the advantage that they are not constrained by the presence of cultivable organisms (Diallo et al., 2021). Recommended genetic target is the capsule gene *ctrA* that detects encapsulated meningococci. In order to detect both, capsulated and also non-capsulated strains, a combined *cnl* and *ctrA* assay may be needed to increase sensitivity.

Bacteria structure

Meningococcal capsule

Meningococcal strains present a polysaccharide capsule with defined functions in the invasion and survival of the bacteria in usually sterile liquids such as blood, spinal fluid, etc., providing resistance to host immune response (Rouphael and Stephens, 2012). The capsule is not present in many strains but it is almost always present in those isolates from invasive disease and for that reason the capsule is considered essential for the survival of the bacteria during the invasive disease (Uria et al., 2008).

The finding that antibodies directed against the capsule played a fundamental role in the protection against invasive meningococcal disease (IMD) (Goldschneider et al., 1969), has led to this polysaccharide envelope forming the basis for the development of vaccines as well as for the classification of the meningococcus in serogroups (Snape and Pollard, 2005).

Although there are 13 serogroups described, a proposal has recently been made to revise the scheme used, which reduces the number of serogroups to 12 and is widely accepted by the scientific community (Harrison et al., 2013); of these, six serogroups, A, B, C, W, X, and Y, cause disease, and are associated with the vast majority of the cases globally (Peterson et al., 2019).

Each serogroup is associated with a chemically distinct capsular polysaccharide; those capsule polysaccharides associated with invasive disease are sialic acid derivatives, with only one exception corresponding to the serogroup A capsule, with a number of repeating units of *N*-acetyl-mannosamine-1-phosphate (Rouphael and Stephens, 2012). The incorporation of sialic acid in the capsule allows the bacteria to be less visible to the immune system, since the sialic acid is also incorporated in the host's cell surfaces. This mimicry reaches its highest degree of expression in the case of serogroup B, where the structure of sialic acid is identical to that of a component of human neuronal cells known as NCAM (neural cell-adhesion molecule). This equality would explain the poor immune response obtained against group B polysaccharide in humans (Hill et al., 2010).

The process of synthesis and translocation to the cell surface is complex, and the genes involved are well identified and located at a single locus termed *cps* (Harrison et al., 2013).

Outer membrane

In meningococci, as in the rest of Gram negative bacteria, the subcapsular cell envelope consists of an outer membrane (OM), a layer of glycan peptide and an inner membrane or cytoplasmic membrane. Most of the interaction of the bacteria with the external environment, including the host's immune response, antimicrobial response, exchange of nutrients and metabolites, etc., takes place at the OM level. For this reason the main components of OM have been extensively analyzed.

The outer membrane would be the subcapsular cell envelope of the bacterium, and it is basically composed of an outer layer of lipooligosaccharide (LOS) and proteins and an inner part composed of phospholipids (Rouphael and Stephens, 2012).

Meningococcal LOS constitute the endotoxin of the bacteria, and three different parts can be distinguished in the LOS of meningococcus: lipid A with hydroxy fatty acid chains and phosphoethanolamine, a core oligosaccharide containing 3-deoxy-D-manno-oct-2-ulosonic acid (KDO) and heptose residues, and a part of short and highly variable oligosaccharides (Jennings et al., 1999). LOS antigenic variability have been the basis for the immunological classification of *N. meningitidis* in different immunotypes (L1–12) (Frasch et al., 1985). Although this classification has been useful for the study of the pathogenesis of the microorganism (Zughaier et al., 2004), it is not a widely used characterization method (Jolley et al., 2007).

At the OM level we can find numerous adhesins. The first step in the infection is the adhesion and attack of the bacteria to the epithelial cells of the mucosa of the upper respiratory tract, colonizing and constituting what is known as the “carrier state” that has already been commented previously. The pili are responsible for a first adhesion to the cells of the mucosa, having proven their role when pilate and non-pilate meningococci are compared (Stephens and McGee, 1981). Additionally, the pili are also involved in the process for the uptake of DNA by meningococci and also facilitating the adherence to erythrocytes.

Also playing a role in adhesion, two types of opacity proteins are found in *N. meningitidis*, known as Opa and Opc (Virji et al., 1994). Opa proteins, also expressed in *Neisseria gonorrhoeae*, are encoded by multiple genes and have four extracellular loops, three of which have variable regions, and sequence diversity within these regions conferring specificity for host receptors (Sadarangani et al., 2011).

In addition, meningococcal strains can express other minor adhesins including NadA (Neisseria adhesin A), NspA (neisserial surface protein A), and the autotransporters MspA (meningococcal serine protease) and Msf (meningococcal surface trimeric autotransporter fibril) (Hollingshead and Tang, 2019). Of these, the most relevant is NadA because it was included in the 4CMenB vaccine formulation, having been studied more in depth (Giuliani et al., 2006).

At the OM level we can find a group of proteins that intervene in the acquisition of iron, which is an essential growth factor for the survival of the bacteria, both in colonization in the nasopharynx and during the disease (Guilhen et al., 2013). They are generically known as “iron-binding proteins” and include HmbR (hemoglobin), TbpA and TbpB (transferrin), HbpA and HbpB (lactoferrin), HpnA and HpnB (hemoglobin-haptoglobin complex), and possible siderophore homologues (Rouphael and Stephens, 2012).

Other well-known proteins found at the OM level are porins, of which *N. meningitidis* expresses two, PorA and PorB. Among the main functions of these proteins is the passage of small nutrients into the bacteria, although they are also involved in host cell interactions since they are target antigens for bactericidal antibodies (Mosaheb and Wetzler, 2018; Peak et al., 2016). Both porins have been used in the characterization of isolates: By using panels of monoclonal antibodies, PorB defined the serotype while PorA allowed classification into serosubtypes. When molecular characterization has been implemented, PorB is no longer used and serosubtypes have been called genosubtypes, based on the peptide sequence of two variable regions (VR1 and VR2) of the protein (Jolley et al., 2007). As we will see later, PorA has been the subject of multiple studies as it is the main component of vaccines against serogroup B, although the great variability of the protein makes it very difficult to achieve a wide coverage of isolates with only this component (Feavers et al., 1992).

With the advent of reverse vaccinology (Rappuoli, 2000) as a vaccine development tool against serogroup B, a good number of new antigens located in OM have been described, which will be later mentioned in the section corresponding to vaccines.

Genetic of *Neisseria meningitidis*

An important characteristic of the meningococcus is the plasticity of its genome that allow a tremendous capability to diversify the phenotype.

Phase variation

Phase variation can be defined as the ON and OFF switching of gene expression mediated by mutations in simple tandem repeats or homopolymeric nucleotide tracts situated upstream region or in the open reading frame of genes (Hollingshead and Tang, 2019; Saunders et al., 2000). A large number of antigens present in the cell envelope, including the polysaccharide capsule, have this genetic regulation mechanisms (Hollingshead and Tang, 2019). This allows the bacteria to regulate the expression of the capsule during the colonization process since it is a structure that, although it facilitates the survival of the bacteria during the invasion process, does not favor the process of adhesion to the cells of the mucosa.

Capsule switching

This phenomenon is possible because meningococcus is naturally competent for genetic transformation, either with DNA from other meningococci or with other species, both of the *Neisseria* genus and others. “Capsule switching” is a horizontal genetic exchange process through transformation and recombination at the locus of serogroup-specific genes involved in capsule biosynthesis, and is favored by a high genetic identity in parts of said genes (Swartley et al., 1997). Therefore, the result is a meningococcus that presents most of the microbiological markers the same as the original strain, but that expresses a capsule of a different serogroup. It constitutes an immune response evasion mechanism, and although it was initially a cause for concern, when starting to use serogroup-specific conjugate vaccines (Castilla et al., 2009), immunization-associated capsule switching has not been observed until now (Snape and Pollard, 2005).

Typing meningococci

Initially the characterization methods were based on an immunological approach, which identified capsule variants (serogroups), outer membrane porins (serotypes and serosubtypes based on PorB and PorA respectively) and lipooligosaccharide (immunotypes). These methods were widely used, and the availability of panels of monoclonal antibodies favored their usefulness and interchangeability (Jolley et al., 2007).

However, because the high variability of most of the proteins that gave an increase number of Non-Typeable strains, but also the need to apply characterization methods in non-culture samples (early treatment with antibiotics results in culture negative samples) led to the development and application of molecular characterization methods that do not produce non-typeability results and that can be used directly on clinical samples, therefore they do not depend on the culture of the meningococcus.

The analysis by multilocus enzyme electrophoresis (MLEE) represent the first step in molecular characterization for meningococci (Caugant et al., 1987), although MLEE was still depending of the culture of the strains. However the methodology was technically complex and presented great difficulties in exchanging information (profiles) between different laboratories, so its use was not wide. In addition, greater accessibility to sequencing methods allowed the development of schemes based on genes or specific fragments thereof, and the emerged genogroups (based in caular genes), PorA types (genosubtypes), FetA types (FetA is a protein that has been a candidate to be included in vaccine preparations), and even PorB types (genotypes) although, as previously commented, their use has disappeared (Jolley et al., 2007). To these typing schemes the Multilocus Locus Sequence Typing (MLST) was added, a methodology that came to replace the MLEE and which had the great advantage of simplicity and portability of results (Maiden et al., 1998). MLST analyzes the variation in housekeeping genes by determining the nucleotide sequence in seven alleles. MLST identify major clones, or clonal complexes, in *N. meningitidis* populations (Maiden et al., 1998) and it has been key for a better understanding of the meningococcal epidemiology, defining hyperinvasive lineages, etc. (Brehony et al., 2007).

More recently, when the Whole Genome Sequence (WGS) has become accessible to many laboratories, MLST is being replaced by core genome MLST (Bratcher et al., 2014) that is based on a core set of genes, that are present in most of the isolates, providing higher resolution than MLST.

Meningococcal epidemiology: Unstable and unpredictable

Even now a days the burden of meningococcal disease is unknown for many parts of the world mainly because of inadequate surveillance, which severely hampers evidence-based immunization policy. This is probably the main reason for the creation of the so-called Global Meningococcal Initiative (GMI), which was established in 2009 (Harrison et al., 2011), and is a forum of independent experts that is organized to develop regional and global recommendations on different aspects of IMD, and that has produced in the last 10 years a wealth of information on relevant aspects of epidemiology in many regions where there was little prior information.

Since IMD epidemiology changes temporally and geographically, a review by region can give a more precise idea about the current situation:

IMD in Africa

In Africa we must distinguish three different sub-regions: North Africa, African Meningitis Belt and the South, each with its own well-defined characteristics.

In the North data are scarce and mainly based in a regional GMI meeting (Borrow et al., 2017b). The data shows that the incidence rate range between 0.09 and 3.6 cases per 10⁵ inhabitants, being the serogroup B predominant followed by serogroup C, and just few group W or Y cases.

The African Meningitis Belt is an area that include 26 countries, from Senegal in the West to Ethiopia in the East, and where large-scale epidemics occur every 5–12 years when IMD attack rates can reach 100–800/100,000 (Mustapha and Harrison, 2018). Historically, the epidemics have been associated with serogroup A strains (LaForce et al., 2007). In 2001 the Meningitis Vaccine Project was created through a collaboration between WHO, the Bill & Melinda Gates Foundation and the Program for Appropriate Technology in Health (PATH) developing a conjugated serogroup A vaccine (MenAfriVac) produced at the Serum Institute of India Pvt., Pune, India (Fall et al., 2018). Between 2010 and November 2015, more than 270 million individuals aged 1–29 years were vaccinated in mass campaigns across 16 countries. This has resulted in a near elimination of serogroup A in the region, although epidemic outbreaks have occurred by serogroups W and X, and more recently by a group C strain not previously described, and which has spread to Nigeria and Niger. producing more than 15,000 cases in Nnadi et al. (2017).

Data coming from SouthAfrica are robust because a well stablish surveillance (Borrow et al., 2017b), with a high proportion of cases associated with serogroup W followed by B (Borrow et al., 2017b).

IMD in Asia

The incidence of IMD in the Asia-Pacific region appears to be low but probably some countries might have some level of underestimation (Borrow et al., 2016).

In China five epidemics associated with serogroup A have been reported between 1938 and 1977 (Borrow et al., 2017b) but serogroup A isolates have been declining following the universal introduction of the MenA polysaccharide vaccine in China in the 1980s (Borrow et al., 2016). Current data indicates a shifts in serogroups distribution, with the emergence of new clones of serogroup B from serogroup C clonal complex (cc) 4821 due to capsular switching (Zhu et al., 2015), and it is also affected by the international spread of serogroup W cc11.

In India, most of the reported cases express serogroup A. The incidence rate has been decreasing during the last years but there is an increasing number of outbreaks and some change in the affected ages has been observed in these outbreaks with a majority of cases between 20 and 30 years old, which could be indicating the appearance of new epidemic clones (Borrow et al., 2016). Nevertheless the lack of a well establish surveillance system in India might be offering underestimation of the actual IMD burden.

In Japan, with a strong surveillance system, the incidence rate is particularly low (0.03 per 10⁵ inhabitants) being the serogroup Y the most prevalent followed by C and B (Borrow et al., 2016).

In the Republic of Korea surveillance for IMD is passive and it appear that there are not many reliable epidemiological data (Borrow et al., 2016).

In the Philippines only the septicemic form, meningococcemia, is reported to the surveillance and response systems probably giving a very skewed view of the actual burden of the IMD. Serogroup A is the most prevalent but serogroup B has also been documented (Borrow et al., 2016).

Australia and New Zealand

In Australia the incidence rate of IMD is around 1.5×10^5 and the serogroups distribution is quite different in different geographical areas: Serogroup B was predominant until 2015 all over the country; however, from that year on, serogroup W had a strong increase, particularly in the North, West and Queensland, which led to the inclusion of MenACWY tetravalent conjugate vaccine in these territories. An exception was the territory of the South, where the increase of W strains was much lower, and serogroup B is still predominant (Parikh et al., 2020).

In New Zealand, serogroup B has historically been the majority, although epidemic outbreaks have been described by serogroup A and C, and more recently an increase in cases associated with serogroup W has been reported, which is part of the global expansion of W cc11 strains (Parikh et al., 2020). In 1991, an epidemic associated with a strain B: 4: P1.7b, 4, cc41/44 began in the country. The incidence rate reached 17.4 per 100,000 population in 2001, and this led to the development of a strain-specific vaccine based on outer membrane vesicles (Taylor-made vaccine concept) that was used between 2004 and 2008, reaching 68% efficacy (Walls et al., 2018).

IMD in America

The incidence rate ranges from 0.01 in Mexico to 0.54 in Brazil, although some Central and South American countries have scarce data and probably an underestimation due to the existence of not very robust surveillance systems, limited laboratory capacity, etc. (Parikh et al., 2020; Sáfadi et al., 2015). There are also significant differences in the serogroup distribution: in Canada serogroup B account for most of the IMD cases, but epidemic outbreaks associated with serogroups C and W has been also reported; in United States an unusual high proportion of serogroup Y cases has been observed since the 1990s of the last century, which has been maintained until today, with serogroup Y representing around a third of cases (Harrison et al., 2009; Parikh et al., 2020) (in a context of a very low rate of incidence). In Central and South America there are great differences between nearby countries, with huge contrasts in incidence rates, which surely reflects fragile surveillance systems, poor accessibility to molecular diagnostic methods, etc. (Sáfadi et al., 2015): while many countries have exceptionally low incidence rates, those with higher incidence rates (Brazil, Argentina and Chile) also have more established surveillance systems, which would give an idea of an underestimation of the actual burden of IMD in the region. In Brazil serogroup C is predominant and a decreasing trend in the incidence rate has been observed recently (Parikh et al., 2020); by contrast, in Argentina and Chile, serogroup W has been predominant during the last years (Abad et al., 2014).

IMD in Europe

In Europe, the incidence rate has been falling during the last 20 years, with an average rate of 0.6 with extremes in the United Kingdom with 1.1 and Bulgaria with 0.1 (Peterson et al., 2019). The serogroup distribution is quite heterogeneous in European countries, with the presence of very diverse vaccination schedules being one of the factors potentially associated with this diversity: serogroup W has increased in a good number of countries, although the most affected have been the United Kingdom and the Netherlands (Krone et al., 2019); around the year 2000, a good number of countries were affected by an epidemic outbreak of serogroup C cc11 strains, while others were not affected or were affected to a lesser extent (Borrow et al., 2013). Nevertheless, serogroup B is still predominant, although the circulating strains associated with clinical cases show some variations in different countries (Abad et al., 2016).

Europe has been the scene of a good number of interventions with vaccines against different serogroups, including the most recent protein vaccines against serogroup B (Davis et al., 2021).

Antibiotics resistance

Except in the case of sulfonamides, with meningococcus rapidly developing resistance, the bacterium has remained susceptible antimicrobials used both clinically and in prophylaxis in close contact of cases.

Attention to a decrease in penicillin susceptibility appeared in the 1980s (Sáez-Nieto et al., 1992) and rapidly this type of isolates was described in a large number of countries, although the level defined as “moderate resistance” remained at similar levels for a long time. However, strains have recently been described, especially isolated in the urogenital tract, in which the penA327 allele is present (Deghmane et al., 2017). This allele has been associated with a significant increase in Minimum Inhibitory Concentration (MIC) against beta-lactams, including 3rd generation cephalosporins. Although the MICs of these strains do not exceed the MIC that defines resistance (250/mL), they are already on the border of it and therefore surveillance should be reinforced to see what its evolution is.

On the other hand, the antibiotics used in prophylaxis of close contacts include both rifampin and ciprofloxacin. Resistance to rifampicin only appears sporadically and no expansion has been detected (Skoczynska et al., 2009). Resistance to ciprofloxacin is still relatively rare except in China, where it is associated with cc4821 strains (Zhao et al., 2020), the majority in the country, and in outbreaks associated with serogroup A in India (John et al., 2013). Although they were already described at the beginning of this century (Block and Vázquez, 2006), only recently an increase in reported cases has been noted, including ciprofloxacin resistant, beta-lactamase producing serogroup Y strains isolated in United States and El Salvador (McNamara et al., 2020; Marín et al., 2021). These strains contain a ROB-1 β -lactamase gene (blaROB-1) most probably acquired from *Haemophilus influenzae*.

Great efforts have been made to organize databases that include alleles associated with resistance genes in order to predict susceptibility in the absence of culture (an increasingly frequent situation in the case of *N. meningitidis*): *penA* gene for penicillin (Taha et al., 2007), *rpoB* gene for rifampicin (Taha et al., 2010) and *gyrA* gene in the case of ciprofloxacin (Hong et al., 2013). All alleles are hosted on the MLST website (Jolley et al., 2018) (<https://pubmlst.org/organisms/neisseria-spp>).

Vaccines

Fig. 1 shows a complete history of the development and authorization of vaccines against IMD that constitute a critical tool for the prevention of the disease.

Already in 1907 a vaccine against IMD was tested with whole cells of *N. meningitidis* killed with heat, although inconclusive results on its effectiveness in the following 30 years, together with the arrival of sulfa drugs, with which it could be prevented but also cured the disease, completely stopped this path of development (Hollingshead and Tang, 2019). In the 1960s Gotschlich et al.

Fig. 1 History of meningococcal vaccines. Vaccines shown on timeline may not be approved/available in all countries and may not all remain available currently (Pizza et al., 2020; Piazza et al., 2021).

(1969) demonstrated the potential of some of the meningococcal capsular polysaccharides to induce a good immune response, which led to the development of monovalent purified polysaccharide vaccines against group C, bivalent against serogroups A and C and finally tetravalent against serogroups A, C, W and Y. However, these vaccines had a number of limitations, such as not being effective in children under 2 years of age, produce short lived, T-cell independent responses and not generate immune memory (Borrow et al., 2013).

The situation improved in the 1980s with the development of glycoconjugate vaccines, in which polysaccharide capsule was coupled to a carrier protein such as tetanus or diphtheria toxoid (Borrow et al., 2013). These conjugated vaccines activate long lived T-cell dependent responses, generating memory B cells, with the possibility to be used in children older than 2 months, generating immune memory effect and with a significance impact in carriers. The first conjugate vaccines were monovalent vaccines against serogroup C, and they were included in a good number of national vaccination schedules worldwide, following the expansion of serogroup C cc11 strains in the late 1990s (Tin Tin Htar et al., 2020).

However, the capsule corresponding to serogroup B has molecular mimicry with the envelope of human neuronal cells and is therefore poorly immunogenic (Freudenburg-de Graaf et al., 2020). Therefore, the development of vaccines against this serogroup has had to be based on an alternative strategy through the search for subcapsular antigens. Gram negative bacteria continuously form the so-called outer membrane vesicles (OMVs) which are small blisters excreted to the outside of the bacteria and which largely reflect the natural composition of the bacteria's own outer membrane (van der Pol et al., 2015). The discovery in the 1970s by Frasci et al. (1976) that the inoculation of meningococcal OMVs produced a protective antibody response was the beginning of what we might call the era of OMV tailor made vaccines. Following this strategy, strain-specific vaccines were developed in Norway, Cuba, Brazil, Chile, to control clonal MenB outbreaks in the 1980s, and also in New Zealand from 2004 to 2008 (Acevedo et al., 2019). However, OMV vaccination only provide protection when the strain associated with an IMD outbreak shares identical or very similar PorA to that included in the vaccine (Acevedo et al., 2019).

With the publication of the first meningococcal genome, but also with and a generalization of the use of genomics and proteomics methods, a more advanced stage is reached in the development of vaccines against serogroup B. Following the strategy of reverse vaccinology (Rappuoli 2000), several new antigens were identified: factor H-binding protein (fHbp), Neisserial adhesin A (NadA), and Neisseria Heparin-Binding Antigen (NHBA). The three antigens have been used to develop a multicomponent vaccine against serogroup B meningococci (Bexsero®) that additionally includes the OMV from the New Zealand vaccine, which expresses a PorA P1.4 (Borrow et al., 2017a). The vaccine has now been implemented in several national immunization programs with very promising data in the England experience with 75% of reduction in IMD cases in age groups eligible for vaccination (Ladhani et al., 2020a).

A second subcapsular vaccine, Trumenba®, containing two fHbp variants (Shirley and Dhillon, 2015) has been also approved for use in adolescents and young adults aged 10–25 years by the FDA in United States and by the EMA in Europe. It has been used in outbreaks control in the United States (Fiorito et al., 2018). There is not available information about effectiveness or impact in “real life.”

Interestingly, Bexsero® vaccine also confers protection against other serogroups (Biolchi et al., 2021), which has also been suggested for Trumenba (Harris et al., 2018).

It has recently been suggested that the use of Bexsero® may produce some level of cross protection against its close relative *Neisseria gonorrhoeae* (Leduc et al., 2020). More studies are necessary to elucidate this finding and to adequately characterize the antigen or antigens involved in this cross-reactivity, but this finding represents an added value in the design of vaccination programs with Bexsero®.

Neisseria gonorrhoeae

Neisseria gonorrhoeae, also known as gonococcus, is the other pathogenic species, together with the meningococcus, appearing in the genus *Neisseria* and it is the etiologic agent of the sexually transmitted disease, gonorrhea. The disease was initially described (or at least symptoms compatible with the clinical characteristics that we know today) 3500 years ago, although the etiological agent of the disease was not described by Albert Neisser until 1789 (Hill et al., 2016). It is a microorganism that has adapted very well to colonize its ecological niche in such a way that, being microaerophilic, it is able under certain conditions of growing under anaerobic conditions (Kellogg et al., 1963).

The disease

N. gonorrhoeae is the etiological agent of a sexually transmitted disease known as gonorrhea, although it can also cause some related pathologies. The gonococcus is able of colonizing a wide range of mucosal surfaces, including the urethra, endocervix, pharynx, conjunctiva, and rectum (Kirkcaldy et al., 2019), being mainly associated with urethritis in men and endocervicitis in women. The disease is asymptomatic in less than 10% of the males infected but most of 50% of women will not develop apparent symptoms (Unemo and Shafer, 2014). Rectal and pharyngeal infections are mostly asymptomatic and usually mainly associated with sexual practices that favor the colonization of these locations. In 2012, the World Health Organization (WHO) estimated that there were 78 million new cases among adults worldwide (Wi et al., 2017).

When the infection is not detected and therefore is not treated, or is not adequately treated, the bacteria can ascend to the upper genital tract and produce severe pathologies such as endometritis, pelvic inflammatory disease, penile edema, and epididymitis, resulting in infertility or ectopic pregnancy these complications affecting mainly women. Conjunctivitis in adults is rarely seen and it is more frequent in the newborn as ophthalmia neonatorum. One form of invasive disease is disseminated gonococcal infection, although it is currently very rare (Bignell and Unemo, 2013). Gonococcal infection has been associated with increased risk for other Sexually Transmitted Infections (STIs) including HIV (Unemo and Ison, 2013).

Detection of the presence of the microorganism in clinical samples: Microbiological diagnosis

Microscopy of clinical samples using either Gram stain or methylene blue stain can be a good diagnostic alternative in laboratories with very limited resources. In symptomatic men, microscopy has a sensitivity of 95% and a specificity of 97%. In endocervical samples, the sensitivity is between 40% and 60%, and in asymptomatic patients or in oropharyngeal and rectal samples, the sensitivity decreases so much that its use is not recommended (Meyer and Buder, 2020).

Culture in a selective medium has been the gold standard and is currently the only diagnostic strategy that allows determining antimicrobial sensitivity, which in the case of *N. gonorrhoeae* acquires great relevance. Its sensitivity in urethral or cervical samples ranges between 85% and 95% and the specificity reaches 100% when the identification of the strains obtained by culture is carried out. However in samples from other locations (conjunctival, rectal, and oropharyngeal samples) these high sensitivity values are not obtained (Meyer and Buder, 2020).

The gonococcus is one of the so-called fastidious microorganisms and because they do not tolerate dehydration, samples have to be inoculated immediately after swab collection onto selective culture media (Unemo and Ison, 2013). To confirm the identification, biochemical (based in enzymatic and metabolic reactions), immunological (coagglutination tests with gonococcal-specific monoclonal antibodies), spectrometric (MALDI-TOF to identify bacteria taken directly from the agar plate), or molecular test (based in Nucleic Acid Amplification Tests (NAATs)) are applied (Meyer and Buder, 2020).

NAATS, based on polymerase chain reaction (PCR) or isothermal transcription-mediated amplification, are the most sensitive and specific method for the detection of *N. gonorrhoeae* in clinical samples, and can be used from swabs collected by the same patient or first-catch urine, often constituting the method of choice for the diagnosis of gonococcus. Its application does not require the presence of viable microorganisms, in most cases they allow automation and consume less time than culture. Additionally, many of those that have been developed allow the simultaneous detection of *N. gonorrhoeae* and other microorganisms associated with Sexually Transmitted Infections (STIs) (Unemo et al., 2019). The main disadvantage of these methods is that they do not allow the analysis of antimicrobial sensitivity, which is critical in the case of *N. gonorrhoeae*, and molecular methods have not been developed for its determination in the absence of culture (Meyer and Buder, 2020).

On the other hand, although NAATs are considered as the diagnostic method of choice globally, a good number of low-income countries have difficult access to this methodology due to its relatively high price, which means that in many of them the diagnosis is based in clinical symptoms and the use of syndromic treatments, which facilitates the risk of development and spread of resistance due to the use of inappropriate treatments (Meyer and Buder, 2020).

Bacteria structure

Capsule

Although gonococcus shares some of the DNA regions involved in the production and transport of capsular polysaccharide in meningococcus, there are other regions that are essential for the synthesis and expression of the polysaccharide that are absent in *N. gonorrhoeae* (Petering et al., 1996). This opens up two possible explanations: one would be the loss of capacity for expression of the capsule by the gonococcus in the course of its evolutionary process of divergence with the meningococcus, and another would be the acquisition by the meningococcus of the ability to express said structure. Although there are not enough data to affirm one thing or the other, it does seem clear that the presence of capsules is not necessary for colonization in mucosa (niche of *N. gonorrhoeae* but also of many non-capsulated strains of *N. meningitidis*) and both its loss and its non-gain, it adapts well to a potential evolutionary process of gonococcus.

Outer membrane

The gonococcal outer membrane contains the most important structures in the colonization and pathogenesis of the microorganism. Bacterial structures located in the OM being involved in attachment and invasion include lipooligosaccharide (LOS), porin, pili (assembled from pilin protein) and opacity associated proteins (Opa proteins) (Unemo et al., 2019).

As with meningococcus, gonococcal LOS has three oligosaccharide (OS) chains, attached to a lipid A core and represent 50% of the mass of the outer membrane of the bacteria, and the number of branches and the length of OSs in each branch vary among gonococcal strains and, indeed, in the same strain during growth in vitro and in vivo (Gulati et al., 2019).

Regarding porins, both gonococcus and meningococcus seem to be the only two species of the genus *Neisseria* that have genes that code for two different types: *porB* and *porA*. However, in the case of gonococcus, the gene *porA* is present but is not expressed due to frameshift and promoter mutations (Derrick et al., 1999). The porin Por is encoded by a single copy of the *porB* gene. There are two major variants of porin protein in *N. gonorrhoeae*, PorB-1A and PorB-1B allowing the classification of the strains in serotypes 1A and 1B, being further classified into serovars through a panel of monoclonal antibodies (Knapp et al., 1984). PorB-1A is often associated with strains causing disseminated gonococcal infection (DGI), being more resistant to complement (C)-dependent killing by normal human serum, while PorB-1B are associated with local gonococcal infection (Shaughnessy et al., 2019). Although gonococcal strains show antigenic differences from PorB, which are the result of mutations or recombination events, the variability is not high. While Gonococcal strains show antigenic differences PorB, which are the result of mutations or recombination events, the variability is not high. Although it was a vaccine antigen candidate a few years ago, the data do not seem to indicate that the antibodies generated are protective in experimental vaccines (Shaughnessy et al., 2019).

Proteins associated with colony opacity (Opa) are a family of proteins that mediate adhesion and invasion of gonococci in human cells (Dehio et al., 1998). Opa proteins play an important role in the pathogenesis of the microorganism, and it has been seen that Opa + gonococci are associated with localized infection (urogenital, cervical and rectal) while Opa-strains are generally isolated from disseminated infection (Draper et al., 1980). Gonococci have a wide repertoire of up to 11 different opa genes coding for distinct opacity proteins which are distinguishable at their variable domains (Bhat et al., 1991). The expression of each gene is governed by independent events that turn on or off the expression of each opa gene. A single strain may express none of the Opa proteins, a single Opa, or a combination of several (Unemo et al., 2019).

Pili are filamentous structures composed of the main subunit (pilin, PilE) with an adhesion associated protein (PilC) located both at the end of the pilus and within the bacterial membrane (Shaughnessy et al., 2019). Gonococcal pili are essential for a correct adhesion to mucous epithelial cells, and they also intervene in self-adhesion and adherence functions with other gonococci, protection from PMNL killing mechanisms, and horizontal genetic transfer (HGT) by DNA transformation (Stohl et al., 2013; Unemo et al., 2019). Their expression seems to be linked to strong selective processes throughout the infection, since all clinical isolates present pili, but they quickly stop expressing them in subcultures in the laboratory (Unemo et al., 2019). The PilE protein is made up of around 160 amino acids and has a highly conserved N-terminal fraction, while the C-terminal is extremely variable (Schoolnik et al., 1984). On the other hand, PilC seems to have a determining role in the entire adhesion process, so its expression would be decisive for it to occur successfully (Shaughnessy et al., 2019).

Other bacterial structures present in OM and of great importance in the pathogenesis of gonococcus are the so-called binding iron-containing host proteins such as transferrin, lactoferrin and hemoglobin. Iron is essential for the growth of the bacteria, and the bacteria obtain it from their host through an acquisition system for transferrin (TbpA–TbpB), one for lactoferrin (LbpA–LbpB) and one for heme (HpuA–HpuB), which can be found, for example, in hemoglobin (Rohde and Dyer, 2003). These systems are known as TonB-dependent Transporters (TdT). The uptake and transport of iron from the outside to the cytoplasm of the bacteria is generally a complex system, which is shared with *N. meningitidis* and other Gram-bacteria (Noinaj et al., 2010).

Finally, other important components of *N. gonorrhoeae* OM are flow pump systems. Gonococcus expresses up to a total of five different systems (MtrC–MtrD–MtrE, MacA–MacB–MtrE, NorM, FarA–FarB–MtrE and MtrF64–66). Some of these flow pump systems are shared with *N. meningitidis*, although the regulatory mechanisms of expression are different in both species, they are different and their role in the pathogenesis and production of antimicrobial resistance could also be different (Shafer et al., 2001; Enríquez et al., 2010).

Genetic of *Neisseria gonorrhoeae*

The gonococcus is an extremely competent bacterium to acquire DNA from other bacteria via horizontal gene transfer (HGT), which translates into a great facility for the acquisition of antimicrobial resistance mechanisms, etc. The transfer of genetic material is mediated by pili, and particularly by type IV-pili. This ability extraordinarily complicates the study of clones due to the instability of the alleles, and suggests that the presence of mixed infections could be more frequent than reported, and that their frequency could be underestimated (Unemo et al., 2019).

Unlike meningococcus, almost all gonococcal strains have a small cryptic plasmid (of unknown function), and the presence of plasmids that code for the production of penicillinase (mostly TEM-1 or TEM-135 β -lactamase), as well as conjugative plasmids that sometimes carry the tetM determinant associated with high resistance to tetracycline. These plasmids have been classified according to a nomenclature based on their place of origin, although at present this classification is rarely little used (Cehovin et al., 2020).

Gonococcus shows high genetic plasticity and even the same isolate can give rise to different antigenic identities after repeated subcultures in the laboratory (Russell et al., 2019). Most of its main surface antigens continually change their sequence and/or use phase variation mechanisms for ON and OFF switching of gene expression. Thus, for example, type IV pili are encoded by pilE genes, and each strain has another set of pilE genes that lack a promoter (pilS) so they are silent genes, which represent a large repository of sequences that can be randomly shuffled to generate new antigenic variants through intra-chromosomal recombination (Haas and Meyer, 1986). This is possible thanks to the addition or loss of a pentanucleotide repeat sequence in the structural gene encoding the amino-terminal leader peptide (Stern and Meyer, 1987).

Typing gonococci

Some of the phenotypic characterization methods that were widely used in the past, such as plasmid profile, auxotyping (profiles of nutritional requirements) and classification in serovars, have fallen into disuse since they did not offer detailed and precise information on the evolution of the clones of isolates with antimicrobial resistance and their level of discrimination could be improved. Molecular typing schemes have very quickly replaced those old traditional phenotypic typing methods due to their greater resolution power, reproducibility and portability and power of analysis of inter-relationships between strains (Unemo and Dillon, 2011).

In the case of *N. gonorrhoeae*, the most commonly used molecular typing schemes have been MLST (Maiden et al., 1998) and *N. gonorrhoeae* Multi-Antigen Sequence Typing (NG-MAST) (Martin et al., 2004). The latter has a significantly higher discriminatory power than the former since, even though it is based on the analysis of the sequence of only two loci (*porB* and *tbpB*), these encode highly variable proteins of the outer membrane exposed to the surface.

However, lower prices both in reagents and equipments and simplifying them have allowed WGS replace these molecular methods in many laboratories, which will improve not only the usual parameters of accuracy and discrimination, allowing to analyze with great precision the appearance and spread of resistance mechanisms (Golparian et al., 2021).

Gonococcal epidemiology

In 2016 the WHO estimated that there would be 86.9 million cases of gonorrhea (global prevalence 0.9%). In the epidemiology of the disease there are a series of determinants such as sexual orientation, socioeconomic, demographic and geographic status, access and quality of sexual education, prevention, tests and diagnoses, as well as the provision of health services (Unemo et al., 2019).

In the United States, the number of gonorrhea cases increased by almost 70% from 2013 ($n = 333,510$) to 2017 ($n = 556,413$) and the proportion of cases in men who have sex with men (MSM) has gone from 4% in 1989 to 38.5% in 2017, which probably reflects, among other factors, a significant improvement in the collection of information on sexual orientation in the United States. In the United States in 2017, the rate of reported cases of gonorrhea was much higher among black populations, American Indians and Alaskan Natives, Native Hawaiians and individuals with Hispanic origin compared with white populations whereas the rate among individuals with Asian origin was half the rate among white individuals (Unemo et al., 2019).

In the EU/EEA, the number of reported cases has increased since 2008, from 29,434 cases to 89,239 cases in 2017, being the United Kingdom, France, the Netherlands and Spain the most affected countries. MSM represented 25–30% of all the cases and it is 57% of the cases reporting sexual orientation, perhaps reflecting that information on sexual orientation in Europe still has a wide room for improvement (Unemo et al., 2019).

Although with many limitations, the WHO has estimated the prevalence of gonorrhea globally and it is the African Region that would have the highest prevalence, followed by the Region of the Americas, the Southeast Asia Region, and the European Region (Rowley et al., 2019), with low-income countries, territories and areas showing the highest prevalence of gonorrhea.

Antibiotics resistance

Gonococcus has been able to develop resistance to all antibiotics used in the first line of treatment over the last 80 years. Gonococcal antimicrobial resistance (AMR), particularly resistance to the only remaining currently recommended antimicrobials, is of grave concern. This is particularly relevant in MSM, where the existence of sexual networks is very frequent, which greatly facilitate the dissemination of these resistances (Kwong et al., 2018).

The evolution of resistance to different antimicrobials used in the treatment of the disease has been extraordinarily rapid, and there is currently a real risk that gonorrhea will become a disease without an antibiotic alternative of choice. Dual antimicrobial therapy (mainly parenteral ceftriaxone plus oral azithromycin) is currently recommended for empirical first-line therapy by the WHO global guidelines but also it is the recommended regimen in most high-income countries (Unemo et al., 2019); however, some other high-income countries like Japan and the United Kingdom are inclined towards the use of monotherapy with ceftriaxone high dose (1 g).

A wide battery of mechanisms responsible for AMR have been described (Table 1), including point mutations, small insertions and deletions in the bacterial chromosome, both in the genes involved and in their regulatory regions. Furthermore, the acquisition of new genetic material on a larger scale, via recombination or through plasmids can also generate AMR.

However, the prediction of resistance from genomic data has not always been possible. It is well known that mosaic structures of the *penA* gene are associated with a lower susceptibility to extended spectrum cephalosporins (ESCs). However, not all mosaic structures explain all cases of resistance to ESCs, and some mosaic alleles of *penA* do not cause a decrease in susceptibility or resistance to these antibiotics. Other factors such as overexpression of the MtrCDE flow pump, mutations in the *poB1b* gene, mutations in the *rpoB* and *rpoD* genes (which code for RNA polymerase subunits) have also been associated with a lower susceptibility to ESCs. Mutations in the 23S rRNA gene (A2059G and C2611T in *Escherichia coli*) are associated with high resistance to azithromycin, as are variants in *mtrR* or its promoter that increase the expression of the MtrCDE efflux pump. Mutations in *rplD*

Table 1 Mechanisms and main determinants of gonococcal antimicrobial resistance.

Sulphonamides	<i>folP</i> gene region (Qvarnstrom and Swedberg, 2006)
Penicillin G	<i>penA</i> mutations producing four -eightfold MIC increases: ✓ Insertion of asparagine: 345 Asp345A (Dowson et al., 1989) ✓ Mosaic <i>penA</i> alleles encoding mosaic PBP2 (A311V, I312M, V316T, etc.) which reduce acylation rate (Unemo et al., 2019). <i>penB</i> (<i>porB1b</i>) mutations (G120K/G120D and A121D) (Olesky et al., 2006). <i>penC</i> (<i>pilQ</i> gene) mutation (E666K) reducing penicillin entry (<i>penB</i> and <i>mtrR</i> mutations are needed for being effective) (Zhao et al., 2005). <i>ponA</i> mutations (L421P in PBP1) (Ropp et al., 2002). Deletion or insertions in the <i>mtrR</i> promoter or in the <i>mtrR</i> gene with an increased expression of the <i>MtrC-MtrD-MtrE</i> efflux pump (Lewis, 2010). Production of plasmid-encoded beta-lactamases (<i>bla</i>_{TEM1} or <i>bla</i>_{TEM135}). Penicillinase-producing plasmids include the Asia, Africa, Toronto, Rio, Nîmes and New Zealand plasmids (Pagotto et al., 2000)
Tetracyclines	<i>rpsJ</i> mutation (V57M) giving ribosomal protection (Hu et al., 2005). <i>penB</i> mutations (G120D and A121D in <i>PorB1b</i>). (Warner et al., 1980). <i>penC</i> (<i>pilQ2</i>) mutation (E666K) reducing tetracycline entry (<i>penB</i> and <i>mtrR</i> mutations are required for the <i>penC</i> mutation effect) (Zhao et al., 2005). Deletion or insertions in the <i>mtrR</i> promoter or in the <i>mtrR</i> gene with an increased expression of the <i>MtrC-MtrD-MtrE</i> efflux pump (Lewis, 2010). Plasmid-mediated tetracycline-resistant N gonorrhoeae (TRNG): the streptococcal tetM determinant responsible for tetracycline resistance is located in a 25.2 MDa plasmid as result of insertion in the gonococcal conjugative plasmid (Morse et al., 1986).
Spectinomycin	16S rRNA (C1192U) reducing the affinity to ribosomal target (Galimand et al., 2000). <i>rpsE</i> mutations (encoding the 30S ribosomal protein S5) (Ilin et al., 2013).
Azithromycin	Mutations in the peptidyltransferase loop in domain V of 23S rRNA alleles (Galarza et al., 2010). Overexpression of the MtrCDE efflux pump associated with mutations in either the <i>mtrR</i> gene or the <i>mtrR</i> promoter (Unemo and Shafer, 2014; Zarantonelli et al., 2001).
Quinolones	<i>gyrA</i> mutations (for example, S91F or D95N or D95G) (Shultz et al., 2001). <i>parC</i> mutations (for example, D86N, S88P and E91K) (Shultz et al., 2001). Overexpression of NorM efflux pump, resulting in decrease susceptibility (Rouquette-Loughlin et al., 2003).
Cephalosporins	Mosaic genes: <i>penA</i> mutations G545S, I312M and V316T mutations are the key for PBP2 with reduced affinity for cephalosporins (Takahata et al., 2006). Non-mosaic: For example A501V or A501T produce increases in the cephalosporins MICs in the order of four times higher (Takahata et al., 2006). Deletion in the <i>mtrR</i> promoter, alterations in amino acid residues 101 and 102 in putative loop 3 of <i>PorB1b</i>, <i>ponA1</i> polymorphism resulting in the alteration L421P have been also associated with reduce susceptibility working with synergy between them (Ohnishi et al., 2011). <i>pena</i> mosaic genes with seven specific alterations associated with high level of resistance (Singh et al., 2020).

have also been associated with decreased susceptibility to this antibiotic, and, conversely, loss-of-function mutations in *mtrC* have been associated with increased susceptibility to several antibiotics, including azithromycin (Sánchez-Busó et al., 2021).

In this sense, WGS is a very effective tool to be able to predict AMR in gonococcus with great precisión (Eyre et al., 2017; Unemo and Shafer, 2014). With WGS, multiple AMR genetic mechanisms, as well as regions of virulence, can be simultaneously analyzed and typed, using the appropriate bioinformatics tools. Compared with traditional epidemiology, it presents a significant improvement in resolution and precision, which allows a comparison of the entire genome of the strains to be analyzed, identifying RAM clones, outbreaks, transmission networks, national and international extension, new resistance mechanisms as well as acquaintances etc. The future in this field involves the organization of platforms that are easy to use by laboratories and in which the comparison of results is accessible and reliable (Sánchez-Busó et al., 2021).

Vaccines

The idea of having an effective vaccine against *N. gonorrhoeae* has acquired great importance in recent years because it would be a very useful tool to stop the advance of antimicrobial resistance and that the infection does not become a disease with little or no treatment option. However, despite the efforts made by different researchers in recent decades, the only slightly optimistic news is that already mentioned for *N. meningitidis* of a certain level of protection against gonorrhea when the 4-component vaccine (Bexsero®) is used in young population and adults (Leduc et al., 2020). The absence of a specific vaccine against gonococcus is explained by a combination of different factors that have made its design and development very complicated up to now. In the first place, gonococcal infection does not confer protection against other re-infections, which does not allow us to define correlates of protection. Second, only recently have animal models of infection been developed (gonococcus is an exclusively human pathogen) in genetically modified female mice (Jerse, 1999).

The absence of a specific vaccine against gonococcus is explained by a combination of different factors that have made its design and development very complicated up to now. First, gonococcal infection does not confer protection against other re-infections, which does not allow the definition of protection correlates. Second, only recently have animal models of infection been developed (gonococcus is an exclusively human pathogen) in genetically modified female mice (Jerse, 1999) and thirdly, and probably as the most relevant factor is the extraordinary antigenic variability that the gonococcus has, with most of those expressed on surfaces being genetically regulated through various mechanisms as has already been commented previously (Russell et al., 2019). And in this regard, *N. gonorrhoeae* has no rival, being able to express different variants of the same antigen in a single strain during passage in the laboratory.

The potential development of an effective vaccine against gonococcus has had a strong push in recent years, the most promising strategies being the use of the mimetic peptide 2C7 (Gulati et al., 2013), use of gonococcal OMV administered vaginally with microencapsulated IL-12 (Liu et al., 2017), and the use of recombinant refolded porin (Zhu et al., 2011).

Both, gonococci and meningococci, constitute pathogenic bacteria of high interest in Public Health and both share a good number of antigens and genetic information (between 80% and 90% homology). However, their adaptive process has followed different paths, probably because they have inhabited different ecological niches with different requirements (Vázquez et al., 1993). However, now it is increasingly common to find gonococcus colonizing extragenital areas such as the nasopharyngeal mucosa and the anal mucosa (Foschi et al., 2020) as well as isolates of *N. meningitidis* in genital and anal mucosa (Retchless et al., 2018; Ladhani et al., 2020b), even in the case of meningococcus, adapting genetically to a more efficient colonization of these new habitats (Seifert (2019); Retchless et al., 2018). This situation produces greater opportunities for genetic exchange between both species, therefore future developments must be closely monitored.

Corynebacterium diphtheriae

Introduction

The genus *Corynebacterium* is located within the order Actinomycetales and has 88 species, of which *C. diphtheriae* is the most important species from the clinical point of view. It is a Gram-positive or Gram-variable, nonmotile, aerobic rod that does not present a capsule or develop spores. In the Gram stain, it usually presents a characteristic distribution that looks like Chinese letters. If stained with methylene blue, purple, or reddish polyphosphate granules can be seen at the ends of the rod (Murphy, 1996).

The solid medium most used for its culture is Tinsdale agar, a selective and differential medium developed in 1947 based on Loeffler medium (Moore and Parsons, 1958). It is a medium that contains potassium tellurite, which inhibits the growth of most of the microbiota of the upper respiratory tract and, by producing SH₂, forms a dark halo around the colony. This halo is observed in different species of *Corynebacterium* sp., which can be differentiated by mass spectrometry or biochemical techniques such as urease production, as described later.

Within the species *C. diphtheriae*, there are four biotypes (*belfanti*, *gravis*, *intermedius*, and *mitis*) that can be distinguished according to the morphology of their colonies, the presence or absence of hemolysis, different biochemical reactions, and by sequencing the 16S ribosomal RNA (Khamis et al., 2005). These biotypes are clinically indistinguishable, so their identification is due to epidemiological and outbreaks control reasons.

C. diphtheriae may carry the *tox* gene, which encodes the diphtheria-causing toxin (Holmes, 2000). This gene, which is transferable to non-toxigenic strains through a lysogenic cycle and site-specific recombination, is repressed by the DtxR protein, which is inactivated in low iron media. The activity of the toxin will be described in the Pathogenesis section. Other species that can carry the *tox* gene are *C. ulcerans* and *C. pseudotuberculosis*.

Historical background

The French physician Pierre Bretonneau observed in the cities Chenonceaux and Tours during several epidemics in the early 19th century that many patients suffered from a hitherto unknown variety of pharyngeal infections. This disease was associated with the development of an observable pseudomembrane in the throat of the patients. For this reason, he named this disease “diphtheria,” which means “made of leather” (English, 1985).

The first isolation of the bacterium was made by Klebs in 1883 from a pseudomembrane, and Loeffler identified it as the etiological agent of the infection in 1884. The existence of exotoxin was first described in 1888 by Roux and Yersin and von Behring and Kitasato developed antitoxin as a treatment (Behring and Kitasato, 1890).

The first vaccine was developed in 1923 by the French veterinarian Gaston Ramon. The development of vaccines and their massive use led to a 99% decrease in incidence in countries such as the USA (Roush and Murphy, 2007).

Epidemiology

Diphtheria mainly affects the pediatric population and immunocompromised adults and was one of the main causes of infant mortality in the prevaccine era. Cutaneous infection, however, has not been diminished by the action of the vaccine, and data on outbreaks in impoverished and resource-limited communities are regularly recorded.

Due to the introduction of the vaccine, the incidence rate of respiratory infection has decreased globally by more than 90% between 1980 and 2000 (Van Panhuis et al., 2013). Despite this, outbreaks continue to occur in environments with limited resources and low vaccination coverage. Currently, the highest incidence data is registered in India, where 50% of the 16,611 cases registered in 2018 by the WHO occurred, followed by Yemen, Nigeria, and Indonesia (WHO (World Health Organization), 2018a). In Europe, the ECDC recorded 63 infections with *C. diphtheriae* or *C. ulcerans* in 2018 (ECDC, 2021), of which only two were respiratory infections. In the United States, the CDC reported 14 cases of diphtheria between 1996 and 2018 (Acosta et al., 2020).

The mortality of diphtheria is 5–17% in the unvaccinated population, even in immunocompetent individuals (Wagner et al., 2012). Diphtheria is currently a notifiable disease. According to WHO data, vaccination coverage was 79% in 2000 and 88% in 2010. The WHO objective is to reach a minimum of 90%, a number that was reached in 2018 in practically the entire northern hemisphere and Australia and New Zealand. The countries of South America, Central and South Africa, as well as countries such as Pakistan, Yemen, the Philippines, Indonesia, and Ukraine, present vaccination coverage of 50–90% (WHO (World Health Organization), 2018b).

Pathogenesis

C. diphtheriae produces a toxin that is the main responsible for the clinical manifestations, with a lethal dose of 100 ng/kg (Gill, 1982). It is an exotoxin made up of two fragments, A and B, of which the second binds to the receptor. Fragment A is composed of the catalytic domain (C domain) and fragment B is divided into two domains: the host cell-binding domain (R domain) and a transmembrane domain (T domain). Fragment A catalyzes the hydrolysis of nicotinamide adenosine dinucleotide (NAD), transferring ADP-ribose to elongation factor 2, which supposes its inhibition. Elongation factor 2 is a protein responsible for coordinating transfer RNA with messenger RNA and ribosome during protein synthesis (Collier, 1975).

Other virulence factors are neuraminidase and trans-sialidase proteins, involved in binding to the host cell. Other proteins that facilitate adherence to epithelial cells of the respiratory tract are the Spa proteins, divided into SpaA–SpaI, adhesins and hemagglutinins (Ton-That and Schneewind, 2003).

Clinical manifestations

Respiratory infection

The incubation period is 2–5 days (WHO (World Health Organization), 2017a,b). Transmission normally occurs by air, although it can also occur through direct contact or fomites. The first symptoms of the infection at the pharyngeal level are nonspecific: sore throat, malaise and low fever. About 70% of patients develop a pseudomembrane in the tonsils in the following days. It can extend into the nasopharynx, larynx, and bronchi or into the nasopharynx and soft palate. Its appearance is cerulean at the beginning and it turns greenish, gray and black. Sometimes this condition is accompanied by swelling of the lymph node and submandibular edema, evolving to a “bull neck” appearance. The main complications of respiratory infection are caused by airflow obstruction, which represents a 10% mortality rate (Dobie and Tobey, 1979).

Systemic infection

There are complications derived from the circulation of diphtheria toxin through the bloodstream, the most common being myocarditis and peripheral neuropathy. Myocardial dysfunction can be accompanied by both bradyarrhythmias and tachyarrhythmias and is seen in 60–70% of deaths during the acute phase of diphtheria (Jayashree et al., 2006). Neuropathy is an autoimmune sequela due to the similarity between the B subunit of the toxin and the extracellular domain of the epidermal growth factor receptor (EGFR). Neurological involvement usually manifests through muscular paralysis or alteration of the facial nerves, which can evolve into bulbar palsy (Hadfield et al., 2000).

Cutaneous infection

Skin infection is usually caused by non-toxigenic strains. Transmission can be through direct contact with the skin or fomites. The most common symptom is an ulcer lesion with possible pseudomembrane formation. Coinfections with other bacteria have also been described, mainly *Staphylococcus aureus* and *Streptococcus pyogenes* (de Benoist et al., 2004).

Diagnosis

For the diagnosis, it is essential to know the epidemiological data, as well as the vaccination status. Differential diagnosis should be made by ruling out other infections with similar symptoms: streptococcal or viral pharyngitis, mononucleosis, oropharyngeal candidiasis, oral syphilis, Vincent angina. . . If there is a suspicion of acute infection, contact precautions should be taken in case of a cutaneous syndrome and, in addition, droplet precautions in a respiratory profile.

Samples indicated for culture are pharyngeal or tonsillar exudates and skin lesions. The sample must be collected with a sterile cotton swab, which will be placed in a tube with a transport medium (Stuart-Amies, Cary-Blair or similar). The sample should be stored at room temperature and processed as soon as possible. Direct Gram staining will be performed and it will be plated on sheep blood agar, and on culture media with tellurite (Tinsdale or modified Loeffler), which inhibits the flora of the upper respiratory tract and also differentiates the *Corynebacterium* sp. colonies with a brown halo. As discussed in the introduction, in the Gram stain, the bacterium appears as a Gram-positive rod-shaped bacillus, usually forming groups in the form of Chinese characters. The culture media will be incubated for 48 h in a 5% CO₂ atmosphere at 37 °C (SEIMC (Sociedad Española de Enfermedades Infecciosas y Microbiología Clínica) et al., 2006).

C. diphtheriae can be differentiated biochemically from *C. ulcerans* and *C. pseudotuberculosis* by the production of urease, which is negative in *C. diphtheriae*, or by the nitrate test, which is positive only for *C. diphtheriae*. However, the latter is not usually used since it is also negative for *C. diphtheriae* serogroup *belfanti*. These three species can also be differentiated by mass spectrometry (MALDI-TOF), with very high levels of identification (Konrad et al., 2010).

In order to determine if the strain is toxigenic, there are several techniques available. Traditionally, a modification of the immunodiffusion test developed by Elek (1949) has been used. This test is based on using a known toxigenic strain as a positive control, a non-toxigenic strain as a negative control, and the test sample. The three strains are plated on an agar medium with a diphtheria antitoxin disk (10 IU) in the center. At 24 h of incubation, a precipitate line is observed in the junction area between the toxin of the test strain and the antitoxin of the disk. This technique has become obsolete due to the appearance of molecular techniques. These allow the *tox* and *rpoB* genes to be detected by real-time PCR, the latter specific for *C. diphtheriae* (Khamis et al., 2005). Enzyme immunoassays can also be performed to detect exotoxin fragment A, although it is a rarely used technique (Engler and Efstratiou, 2000).

Therapy

The main treatment for respiratory diphtheria is the use of antitoxin. Its usual dose is 20,000–40,000 U (up to 120,000 U in severe or advanced cases) and is administered intravenously or intramuscularly. Additionally, the use of antibiotics can prevent toxin production and reduce transmission. CDC guidelines advise 14 days of oral or parenteral erythromycin at a dose of 40 mg/kg/day or intramuscular penicillin G (600,000 U twice daily; at half dose in children <10 kg) (CDC (Centers for Disease Control and Prevention), 2021).

In the management of respiratory diphtheria, it is also essential to ensure airflow. For this, endotracheal intubation or tracheostomy can be used in severe cases.

Cutaneous diphtheria is treated only with antibiotics; the use of antitoxin is not useful because most cases are caused by non-toxigenic strains. The usual treatment is a beta-lactam alone or in combination with an aminoglycoside. Vancomycin can also be used as a substitute for beta-lactam (Zou et al., 2020). However, there is little information on the treatment of this type of diphtheria; therefore, there are no specific recommendations on dosage or duration of treatment.

Prophylaxis

The main prophylaxis is vaccination, which is 97% effective in preventing the development of an infection by a toxigenic strain (CDC (Centers for Disease Control and Prevention), 2021). Four doses (three in adults) are necessary to reach the level of 0.1 IU/mL of antitoxin considered protective against infection (Galazka and Roberson, 1996). A British study showed that, in the absence of booster doses, the protection of the vaccine in those over 60 was reduced by 50% (Myers et al., 1982).

The vaccine has been administered since 1948 in combination with tetanus toxoid and acellular remains of *B. pertussis* (DTPa). According to the vaccination schedule, three doses should be administered between 4 and 8 weeks from 2 months of age and up to 1 year of life. In Spain, the vaccination calendar establishes the doses at 2, 4 and 11 months. Subsequently, a fourth dose will be administered at 6 years of age and a fifth at 14 years with possible successive doses every 10 years. In patients who have acquired the infection, vaccination is also recommended as natural immunity may not reach protective levels. In pregnant women, a dose of DTaP is recommended at 27 weeks of gestation (SNS (Sistema Nacional de Salud), 2021).

In the case of a patient with a respiratory infection, precautionary measures should be instituted to avoid droplet transmission. These should be maintained until two cultures of samples taken in consecutive days are negative after the end of the 2 weeks of antibiotic therapy. If a person comes into contact with a patient with a respiratory infection, antibiotic prophylaxis will be administered regardless of their vaccination status. Prophylaxis can be performed with erythromycin (7–10 days) or a single intramuscular dose of benzathine penicillin G (CDC (Centers for Disease Control and Prevention), 2021).

Corynebacterium spp.

Coryneform bacteria are part of the skin microbiota of humans and some animals, as well as being distributed in the environment. They can also colonize surfaces and materials forming a biofilm, which is very important when it comes to medical or healthcare equipment. Due to its role in the microbiota, its finding in the microbiology laboratory is often interpreted as contamination without clinical significance. However, since the beginning of the century, there has been increasing evidence on the etiological role

of coryneform bacteria in some infections, especially in the nosocomial context and in immunocompromised patients (Funke and Bernard, 1999). The most frequent corynebacterial infections in the health care setting are infections associated with implantation of devices, catheter-related septicemia, endocarditis, peritonitis in dialysis patients, etc. On the other hand, some corynebacteria that have been described as recognized pathogens in animals have been associated with certain zoonoses in humans. These infections are usually acquired in the community and can present as skin, genitourinary, or oropharyngeal infections.

As general characteristics, corynebacteria are irregularly shaped, pleomorphic, non-spore-forming aerobic Gram-positive rods. As previously described, in the Gram stain they usually present a very characteristic Chinese letter-shaped distribution.

Fermentative corynebacteria: Nonlipophilic group

The classification of corynebacteria is based on their ability to ferment and to grow or not in the presence of lipids such as Tween 80. Fermentative corynebacteria can ferment sugars and produce acids. Non-fermentative corynebacteria make up a group that will not be treated due to their practically harmless role for humans, forming part of the respiratory microbiota.

Corynebacterium ulcerans and Corynebacterium pseudotuberculosis

These are two pathogenic bacteria in animals that can occasionally cause zoonotic infections in humans. Both can produce a toxin similar to that of *C. diphtheriae*.

C. ulcerans is associated with skin ulcers and pharyngitis, as are *C. diphtheriae* cutaneous infections. In fact, in some countries such as the United Kingdom, it has been postulated as a more common diphtheria agent than *C. diphtheriae* (Both et al., 2015). *C. ulcerans* is similar to *C. diphtheriae* therefore not only in clinical presentation but also in diagnostic and treatment methods. The difference is that human-to-human transmission is unclear and seems unlikely (Konrad et al., 2015).

C. pseudotuberculosis is a common pathogen of cattle and its infection in humans is rare and is related to farmers or veterinarians (Dorella et al., 2006). It causes the same condition as in animals, lymphadenitis, and it can also produce an infection similar to *C. diphtheriae*. In addition to the antibiotic treatment already mentioned, it may be necessary to remove the affected nodes.

Corynebacterium striatum

It is a ubiquitous bacterium, which is part of the skin microbiota in humans. For this reason, it has always been considered a contaminant; however, it has been described as the main pathogen in immunosuppressed patients, COPD patients or catheter carriers. This is related to its ability to produce biofilms, which usually means that the infections are mainly nosocomial. Although less frequently, its role as an etiological agent of infections in immunocompetent patients has also been described, producing septic arthritis, osteomyelitis, empyema and endocarditis, among others (Lee et al., 2018).

Resistance to penicillin, erythromycin, clindamycin and ciprofloxacin has been described. It is usually treated with vancomycin in hospitalized patients or oral daptomycin; however, resistance has also begun to be observed (McMullen et al., 2017).

Corynebacterium minutissimum

It is also a bacterium present on human skin, and for years it has been considered the cause of erythrasma; however, their role is controversial and in doubt. Erythrasma is a skin condition, especially in intertrigo folds: fingers, armpits and groin. It causes redness in the area and itching. The lesions acquire a characteristic coral-reddish color under the ultraviolet light of Wood lamp (Groves et al., 2021). Like *C. striatum*, it can cause endocarditis in immunosuppressed or catheter patients, pyelonephritis, and skin abscesses (Ahmad and Ahmad, 2005).

Corynebacterium glucuronolyticum

It is part of the microbiota of the genitourinary tract of animals and humans and can sometimes act as an opportunistic pathogen (Ruiz-Pino et al., 2019). It has traditionally been found in semen samples from men and is associated with non-gonococcal male urethritis and chronic prostatitis (Riegel et al., 1995). It is sensitive to beta-lactams and vancomycin.

Corynebacterium amycolatum

It is part of the skin microbiota of healthy individuals, and it is the non-lipophilic corynebacterium most frequently isolated in clinical samples (Bernard et al., 2002). It has been associated with catheter infections, nosocomial endocarditis, and septic arthritis. It is usually treated with vancomycin and daptomycin; it is also sensitive to beta-lactams, macrolides and quinolones (Dragomirescu et al., 2020).

Corynebacterium xerosis

Also present in the mucocutaneous microbiota of humans, it can be considered an opportunistic pathogen in immunocompromised patients. Although rare, endocarditis, septic arthritis, and osteomyelitis have been reported (Eliakim et al., 1983). Infections are also related to a surgical history.

Fermentative corynebacteria: Lipophilic group

This group of microorganisms is characterized by their slow and fastidious growth, with small non-hemolytic colonies (Funke and Bernard, 1999). Its growth is favored if lipids such as Tween 80 are added to the culture medium, which gives the group its name.

Corynebacterium urealyticum

This is another bacterium that usually colonizes the skin of hospitalized patients. It is related to urinary tract infections, such as encrusting cystitis, especially in patients with bladder catheters. The clinic is characterized by pyuria, leukocyturia, and struvite crystals in the urine (Costales et al., 2019).

Treatment is usually carried out with vancomycin since it has resistance to beta-lactams and variable sensitivity to quinolones and macrolides. In addition, the removal of incrustations in the bladder mucosa can be considered in cases of encrusting cystitis.

Corynebacterium jeikeium

It usually colonizes the skin of hospitalized patients and can cause infection in those with risk factors such as immunosuppression and the use of a catheter or prosthetic valves. The most usual symptoms are peritonitis, external otitis, osteomyelitis and postsurgical infections (Mookadam et al., 2006). It is a corynebacterium with high resistance to beta-lactams, aminoglycosides and macrolides, which is why it is usually treated with vancomycin or daptomycin.

Other corynebacteria

Arcanobacterium haemolyticum

Formerly named *Corynebacterium haemolyticum*, it is described as an etiological agent of pharyngitis and skin infections. It is a nonmotile, Gram-positive or Gram-variable, catalase-negative and non-spore-forming bacillus. On blood agar it produces weak β -hemolysis and does not grow well in tellurite-rich media, which differentiates it from *C. diphtheriae*.

Pharyngitis caused by *A. haemolyticum* is clinically indistinguishable from streptococcal pharyngitis and usually includes a scarlatiniform rash on the neck, trunk, and extremities. Together with skin infections, polymicrobial wound infections and cellulitis have been described. In addition to these infections, others that can occur less frequently are necrotizing fasciitis, osteomyelitis, and endocarditis (Vu and Rajnik, 2021).

Treatment can be with vancomycin, clindamycin, or doxycycline. It is sensitive to beta-lactams, but they show low activity in vivo, probably due to the difficulty of intracellular penetration.

Turicella otitidis

It is part of the microbiota of the ear canal, which is why it has been associated with otitis media. However, its implication is questioned since it is isolated from both patients and healthy individuals. It has been described as a cause of mastoiditis and atrial abscess (von Graevenitz and Funke, 2014). It is sensitive to beta-lactams, vancomycin, linezolid, and quinolones.

Rothia mucilaginosa

- It is a bacterium of the oral microbiota, rarely identified as a causative agent of bacteremia or endocarditis in hematological patients and pneumonia in immunosuppressed patients (Maraki and Papadakis, 2015).

Trueperella bernardiae

It is a rare pathogen in humans. It has been associated with sporadic cases of bacteremia, necrotizing fasciitis and joint, wound and ophthalmic infections (Rattes et al., 2016).

Listeria monocytogenes

Introduction

L. monocytogenes is the main pathogen of the genus *Listeria*, which contains two other species that may be opportunistic pathogens (*L. ivanovii* and *L. grayi*) and 14 more non-pathogenic species (Orsi and Wiedmann, 2016). It is a non-sporulated Gram-positive rod, facultative anaerobic and mobile due to the presence of peritrichous flagella. However, it has often been described as Gram-variable and even Gram-negative because it can discolor relatively easily. On blood agar it forms round white colonies and produces weak beta-hemolysis. It is halophilic and psychrophilic, capable of growing in refrigeration temperatures (4–8 °C), although its optimum growth temperature is 30–37 °C. Biochemically it is characterized by being oxidase negative and catalase-positive. It presents different serotypes, of which the most predominant in gastrointestinal infections are 1/2a and 1/2b, while 4b is an invasive serotype. These serotypes are differentiated according to the type of somatic antigen and flagellar antigen (Datta and Burall, 2018).

Historical background

In 1926, the South African doctor Everitt G. D. Murray and his collaborators Webb and Swann studied in Cambridge an epidemic that affected animals, mainly rabbits. Murray described the presence of a bacillus in the observed samples and, because this disease was accompanied by monocytosis, he named this bacterium *Bacterium monocytogenes* (Murray et al., 1926). In 1940 it was officially named *Listeria monocytogenes*, based on the name *Listerella hepatolytica* given to it by physician James H. H. Pirie in 1927 in honor of Joseph Lister, a surgeon committed to antisepsis (Pirie, 1940).

Epidemiology

L. monocytogenes is normally transmitted through the consumption of contaminated food and can produce small outbreaks. The most related foods are unpasteurized dairy, smoked fish, ice cream, pâté, and raw vegetables. In Europe, it is the third bacterium that causes the most deaths related to food contamination, after non-typhoid *S. enterica* and *Campylobacter* spp. (WHO (World Health Organization), 2017a,b). In 2017, the CDC recorded 887 cases of listeriosis in the US (CDC (Centers for Disease Control and Prevention), 2017) and the ECDC 2502 cases in Europe, with Germany, France and Spain as the countries with the highest incidence (ECDC (European Centre for Disease Prevention and Control), 2020).

Pathogenesis

It is a facultative intracellular pathogen with virulence factors that facilitate its entry into cells, as well as the evasion of the immune response. The main proteins it produces for this are internalin A (InlA) and listeriolysin O (LLO). The first allows it to invade host cells by endocytosis; the second is activated in the acidic environment of the phagosome and prevents the formation of the phagolysosome, slowing down the cellular response (Nguyen et al., 2019).

Normally, the route of entry is the gastrointestinal tract. For *L. monocytogenes* to survive, the stomach pH must be greater than 3. Once in the duodenum, the bacteria can cross the gastrointestinal membrane and spread via bloodstream through the lymph nodes. It presents tropism for the liver and spleen and can cross the blood-brain barrier in certain cases, moving retrogradely through the nerve axons to the brain parenchyma. This happens when *L. monocytogenes* travels within lymphocytes by the method called “Trojan horse” (Drevets and Bronze, 2008). In this same way, it can also cross the transplacental barrier.

Clinical manifestations

Gastrointestinal infection

It is the most common presentation in immunocompetent individuals, both adults and the pediatric population. The incubation period is less than 24 h and usually presents a self-limited condition lasting 1–3 days, although in some cases it can last up to 7 days (Ooi and Lorber, 2005). The most common symptoms are nausea, diarrhea, fever and headache.

Listeriosis in pregnancy

16% of invasive listeriosis cases occur in pregnant women, making pregnancy a risk factor for developing invasive listeriosis (Goulet et al., 2012). The main risk in these cases is a neonatal infection due to vertical transmission, which can lead to preterm delivery, neonatal listeriosis or stillbirth. During pregnancy, cellular immunity may decline in the third trimester, making it the most likely time for a woman to become infected with *L. monocytogenes*. However, the prognosis is worse in the first trimester of pregnancy (Wang et al., 2021).

The incubation period is longer than in gastrointestinal infection and can last 1–2 months. Symptoms in the mother are nonspecific: fever, flu-like syndrome, abdominal pain, diarrhea, contractions... By crossing the placenta, *L. monocytogenes* causes chorioamnionitis and neonatal infection, which can also result in premature delivery, spontaneous abortion or fetal death. The infections most associated with neonatal listeriosis are pneumonia, meningitis, and bacteremia. A rare condition but associated with neonatal listeriosis is infantile septate granulomatosis, which is characterized by the presence of microabscesses and hepatosplenic granulomas. The mortality of neonatal listeriosis is around 20–30% (Lamont et al., 2011).

Bacteremia

It is the most common presentation of invasive listeriosis and is practically restricted to immunocompromised patients or those over 70 years of age. It usually presents with nonspecific symptoms (fever, tachycardia, nausea) 5–10 days after infection. It can lead to neuroinfection, native or prosthetic valve endocarditis, or septic arthritis (Goulet et al., 2012).

Neuroinfection

L. monocytogenes is one of the most common pathogens in CNS infections, especially in patients with risk factors such as immunosuppression or diabetes (Brouwer and van de Beek, 2018). The most common condition is meningoencephalitis, where a parenchymal infection occurs in the cerebral cortex before a suppurative process and the development of abscesses. It presents with altered consciousness and cognitive dysfunction, similar to herpetic encephalitis. Another less common condition is rhombencephalitis, which affects the brainstem and presents with a prodromal onset of 4 days followed by abrupt onset asymmetric cranial

neuropathy, hemiparesis and cerebellar symptoms. It is associated with respiratory failure (40%) and high mortality. It can also affect the brain stem (unlike other bacteria) and cause brain abscesses. The incubation period is 10–14 days and the most common symptoms are fever, headache, chills, myalgia, and diarrhea. In addition, neuropathies and neck stiffness may occur. Mortality is 30%, and about 50% of surviving patients have neurological sequelae (Mylonakis et al., 1998).

Diagnosis

Depending on the clinical presentation, *L. monocytogenes* can be isolated in blood cultures or cultures of CSF, amniotic fluid, placenta. . . In cases of suspected neurolisteriosis, it can be detected by PCR in the CSF. The Gram stain has low sensitivity in both CSF (30%) and blood (45%) (Shoham and Bartlett, 2018). *L. monocytogenes* can be identified by mass spectrometry or by biochemical tests, which can also be used to differentiate it from *L. ivanovii* (xylose positive) and *L. grayi* (mannitol positive) (Pine et al., 1989). In addition, the CAMP hemolysis test is positive. This test consists of a synergy of *S. aureus* β -hemolysis on sheep red blood cells, which is enhanced when sown together with *L. monocytogenes*. The name of this test is an acronym of the authors who described it when observing it in group B streptococci such as *Streptococcus agalactiae*: Christie, Atkins and Munch-Petersen (Christie et al., 1944).

Therapy

Due to its self-limited nature, listeriosis often does not require antibiotic treatment, but simply support. In severe cases, different antibiotics have been used; however, there are no official guidelines for the management of the infection, so this is a glance over the traditional and more frequent use in the literature. The treatment of choice is ampicillin or amoxicillin (2 g IV/4 h) for 2 weeks in pregnant women, 3 in cases of meningoenzephalitis and 6 in rhomboencephalitis and endocarditis. Gentamicin (5 mg/kg/24 h) is usually associated, especially if the cellular immune response is affected (Pagliano et al., 2017).

Second-line treatment; for example, in cases of penicillin intolerance, it is erythromycin, cotrimoxazole or meropenem. Cotrimoxazole is contraindicated in the first trimester of pregnancy since it can alter the cardiac and CNS development of the fetus (Hernández-Díaz et al., 2001). Gastrointestinal infection cases, being normally self-limited, do not require antibiotic treatment.

Prophylaxis

Prophylaxis is mainly based on avoiding the consumption of potentially contaminated food, such as raw, smoked or undercooked fish and meat, pâtés, raw vegetables such as prepared salads, unpasteurized milk or cheeses. . . It is also advisable not to store these foods in the refrigerator for more than 4–7 days (Iwamoto et al., 2014).

Bacillus anthracis

Introduction

B. anthracis is a large Gram-positive rod ($1.5 \times 5 \mu\text{m}$), spore-forming and non-motile. On blood agar the colonies are white and have irregular edges, which has traditionally been called the “Medusa head” shape. On Gram stain, the bacilli tend to form chains and may have a faded center. The spores are non-deforming. Apart from these characteristics, it differs from other species of the genus by being catalase positive.

Historical background

During the 19th century, numerous physicians and biologists in Europe studied anthrax disease. The German physician Alois Pollender is considered the discoverer of the etiological agent in 1849 when he described that elongated cylinders were always observed in the samples of anthrax lesions. The microbiologist Ferdinand Cohn proposed that anthrax was then caused by a bacterium, which he named *Bacillus anthracis* (from Greek “anthrax,” “charcoal”). Robert Koch proved Cohn’s hypothesis in 1877 by isolating the bacterium, inoculating it into a healthy animal, and observing the onset of the disease. From this event, Koch developed the postulates that allow establishing the relationship between a microorganism and a disease (Koch, 1876). In 1881, Pasteur developed a veterinary vaccine from non-virulent strains (Scorpio et al., 2006).

Epidemiology

It is a zoonosis that affects 2000–20,000 humans per year and has a worldwide distribution, with special incidence in Central African, Central American and Asian countries (WHO (World Health Organization), 2008). It was precisely in Africa that the largest anthrax epidemic in humans was recorded, which occurred between 1979 and 1985 in Zimbabwe, with more than 10,000 cases and 182 deaths (Clegg et al., 2007).

Spores are the infectious form of the disease, and humans often acquire it from exposure to infected animals or contaminated animal products. The route of entry of the spores can be by inhalation of spore-loaded dust, by ingestion of contaminated meat or water or skin through injuries (WHO (World Health Organization), 2008).

It is convenient to remember that when an infected animal dies, humans can become contaminated by ingesting vegetative forms that may be in the meat. Furthermore, these vegetative forms can be distributed by flies and transmitted to humans or other animals. Finally, some scavengers such as vultures can shed *B. anthracis* spores in their feces after feeding on these infected carcasses.

When the route of entry is the ingestion of contaminated meat, *B. anthracis* usually produces a gastrointestinal infection.

Medical and social interest in anthrax grew in 2001 when *B. anthracis* spores were first used as a biological weapon. These were sent in mailing envelopes and resulted in 22 cases of anthrax, with 5 deaths (Borio et al., 2001).

Pathogenesis

The main virulence factor of *B. anthracis* is its production of exotoxins. These are encoded in the plasmid pX01 and have been used both in the diagnosis of the disease and in the development of vaccines. The toxins are: edema toxin and lethal toxin (Tournier and Rougeaux, 2020).

Edema toxin is composed of an “edema factor” linked to a protective antigen and it is an adenylate cyclase that alters cellular function, especially those associated with innate immunity. Therefore, phagocytosis, the production of free radicals, and the performance of lymphocytes and macrophages are altered. It also produces an increase in permeability and hypotension, which is why it is called edema toxin.

The lethal toxin is a calmodulin-dependent zinc metalloprotease that will also alter cell function. This toxin also increases vascular permeability; in addition, it produces lesions in the intestinal epithelium that can lead to superinfections by enteropathogenic bacteria.

Clinical manifestations

Cutaneous infection

The incubation period, normally after contact with the infected animal, is 1–5 days. The site of inoculation is usually a small trauma to the skin of the head, neck, or extremities, and will result in an itchy papule. Small vesicles with a fluid rich in bacteria form around the papule. When the vesicles rupture, an ulcer forms that blackens over time and a painless induration of the skin or edema forms around it. This is important for the diagnosis since the rest of cutaneous infections by other microorganisms do not usually form edema or induration of the lesion. The ulcer usually heals spontaneously within 2–3 weeks and the eschar falls off without scarring. Although it is a local infection and there is no bacteremia, it is usually accompanied by headache and low-grade fever. The lethality of untreated infection is 15–20% and is almost nil with treatment (Dogany et al., 2010).

Respiratory infection

Disease caused by accidental inhalation is extremely rare; however, it is of great importance because it is practically always lethal, even with antiserum treatment (Holty et al., 2006). The incubation period is usually less than a week. In order to be inhaled and to gain access to the bronchioles and alveoli, spores must measure less than 5 µm. There the spores are phagocytosed and travel to the mediastinal lymph nodes. This first phase, called the early prodromal phase, is characterized by flu-like symptoms with low-grade fever, myalgia, and malaise (Lucey, 2005). It is followed by the intermediate progressive phase with high fever, intense sweating and respiratory symptoms: dyspnea, chest pain and syncope. The third and final phase is the fulminant late phase, which presents with bacteremia, sepsis, and multiple organ failure. Patients in this phase require intubation and mortality in less than 24 h is high (Sweeney et al., 2011).

Gastrointestinal infection

This presentation, which is the most common in animals, is quite rare in humans and is restricted to rural areas of developing countries. The infection period is 1–5 days and may present an oropharyngeal or intestinal presentation. The first presents symptoms such as dysphagia, odynophagia and pharyngitis. In addition, there is usually fever, lymphadenitis, and edema of the face and neck. Sometimes an ulcer may develop in the mouth or pharynx; for example, in the tonsils. These ulcers are usually covered with a pseudomembrane, which facilitates their diagnosis. The intestinal disease presents with nausea, vomiting and abdominal pain, in addition to fever and diarrhea with bloody stools. Gastrointestinal infection is usually associated with bacteremia and sepsis and has a mortality of 40% (Beatty et al., 2003).

Central nervous system infection

One of the possible complications of *B. anthracis* bacteremia is meningitis. It is rare since it occurs in 30% of cases of inhalational anthrax, which is uncommon. The most frequent symptoms are acute headache, fever, vomiting, altered mental status and neurological signs (Katharios-Lanwermyer et al., 2016). In addition, it is usually accompanied by edema and parenchymal cerebral hemorrhage or subarachnoid hemorrhage, atypical signs in meningitis caused by other microorganisms. It is therefore a presentation with high mortality that requires antibiotic combination therapy to increase survival. Microbiological diagnosis can be made from CSF by staining, PCR, or culture.

Diagnosis

In skin infection, the clinical diagnosis must be made from a differential diagnosis that allows ruling out other diseases that present with similar lesions, such as those caused by *Francisella tularensis*, *Streptobacillus moniliformis*, *Blastomyces* sp. and other skin fungi and rickettsiae. The features that should guide the suspicion of *B. anthracis* are the painless lesion and the large surrounding edema.

Suitable samples for the biological diagnosis of skin infection are aspirate of the gallbladder fluid, smear from the edge of an eschar, or biopsy of the lesion (CDC (Centers for Disease Control and Prevention), 2020). In cases of suspected sepsis or systemic infection, blood cultures are recommended due to their high sensitivity. If there is pulmonary involvement, it is advisable to obtain pleural fluid and not sputum, since a productive cough is not usually observed. Identification is usually carried out in reference laboratories and can be done by PCR or direct immunofluorescence (ASM (American Society for Microbiology), 2017). Other less used but useful techniques are serological techniques such as ELISA, which make it possible to detect antibodies against the protective antigen. The main drawbacks are that these techniques are not useful in the first period of the disease, since they become positive from 1 week after the onset of symptoms.

Therapy

Antibiotic treatment has historically been based on the use of penicillin. However, due to increased resistance, other treatments are currently used depending on whether anthrax is cutaneous, respiratory, or systemic (Hendricks et al., 2014). *B. anthracis* is sensitive to first-generation cephalosporins, carbapenems, clindamycin, macrolides, fluoroquinolones, aminoglycosides, tetracyclines, rifampin, daptomycin, and linezolid. In cases of cutaneous anthrax, the treatment of choice is oral, with fluoroquinolones or doxycycline for 7–10 days. In severe cases or with CNS involvement, the intravenous combination of a fluoroquinolone with a carbapenem (or penicillin if sensitive) and a protein synthesis inhibitor, such as linezolid, clindamycin, or rifampicin is recommended. The duration can be from 2 to 3 weeks to 2 months depending on the clinic.

Prophylaxis

The mainline of prophylaxis is the veterinary vaccine, which has been used for decades and has led to a great decrease in cases in both animals and humans.

There is also a vaccine for humans that was licensed in the US in 1970, developed by Wright and his colleagues. It is a vaccine that contains the protective antigen (PA) adsorbed on an aluminum hydroxide gel. This vaccine is used to immunize mainly exposed professionals (veterinarians, farmers) and soldiers to prevent possible bioterrorist attacks. This vaccine is for intramuscular administration to avoid adverse effects locally from subcutaneous administration. The dosing regimen is 0, 1, 6, 12 and 18 months, in addition to annual boosters (Bower et al., 2019).

Bacillus spp.

Introduction

The rest of the species in the genus *Bacillus* are spore-forming bacilli, Gram-positive or Gram-variable, facultative anaerobes. In blood agar cultures they usually show beta-hemolysis, unlike *B. anthracis*. They are ubiquitously distributed as they tolerate extreme temperatures, desiccation, and heat. For this reason, they have been used for decades in the industry to control sterilization and hygiene processes (e.g., *B. subtilis*, *B. stearothermophilus*) (Turnbull, 1996).

Normally, the isolation of *Bacillus* spp. in clinical samples it is considered contamination since they are not usually identified as etiological agents of infections. The syndromes most related to species of this genus are food poisoning and infections at different levels: cutaneous infection, meningitis and systemic infection. *B. cereus* is the main *Bacillus* species responsible for these syndromes, so it will be the main object study in this chapter.

Clinical manifestations

Food poisoning

Food poisoning is caused by the ingestion of toxins produced by different species, mainly *B. cereus*, and is widely described, although it is rare compared to gastrointestinal infections produced by *Campylobacter*, *Salmonella* or *Clostridioides* genera. There are two types of toxins: emetic toxin and diarrheal toxin. The emetic toxin is a heat-stable peptide toxin found primarily in rice and is similar to the enterotoxin of *S. aureus*. It acts quickly (<6 h) and produces a disease that occurs with vomiting, cramps and diarrhea in some cases. The syndrome is usually self-limited in less than 24 h. The diarrheal toxin is polypeptidic and has a higher molecular weight than the emetic toxin. It is heat-labile, so it can be removed by heating food to a high temperature. It takes 6–18 h to act and produces acute diarrhea that usually remits spontaneously in less than 24 h (Jessberger et al., 2020).

Systemic infection

Although rare, the etiological role of *B. cereus* in systemic infections has been described. Its role as an infectious agent is highly controversial, since, as said before, it is often considered a contaminating agent. However, there are studies where it has been considered the causal agent of bacteremia and skin infections, mainly in patients with central venous catheters (Weber et al., 1989). Likewise, infections by *Bacillus* spp. in neonates by perinatal transmission have been described.

Cutaneous and mucosal infection

B. cereus has been associated with wound infections and cellulitis, usually after severe trauma and skin erosion or with postoperative wounds. These are not normally serious infections, but they make wound healing difficult and can favor the appearance of superinfections (Ehling-Schulz et al., 2019).

Central nervous system infection

CNS infection is rare and is related to the implantation of CSF bypass valves. It can present with encephalitis, meningitis and brain abscesses, especially in neutropenic patients (Gaur et al., 2001).

Diagnosis

In cases of gastrointestinal infection, the search for *Bacillus* spp. in stool samples is not routinely performed in the laboratory, nor are there any commercially available toxin detection techniques. For these reasons, the diagnosis of food poisoning is usually clinical and based on the patient's history, and not microbiological.

Therapy

The main treatment of food poisoning is supportive, ensuring the rehydration of the patient. For catheter-associated skin infections or bacteremia, the infected catheter or prosthetic material must be removed. *B. cereus* is resistant to penicillins and cephalosporins. In the case of using antibiotics, it is recommended to use ciprofloxacin, vancomycin, linezolid or carbapenems. Clindamycin efficacy has been observed in cases of native valve endocarditis (Wright, 2016).

Prophylaxis

Proper cooking of food eliminates viable *Bacillus* spp. and it destroys the diarrheal toxin, but not the emetic. It is advisable to avoid leaving the rice already cooked at room temperature and it is recommended to refrigerate it as soon as possible since the production of toxins is inhibited at low temperatures (Ehling-Schulz et al., 2019).

Erysipelothrix rhusiopathiae

Introduction

E. rhusiopathiae is a facultative anaerobic, non-sporulated Gram-positive or Gram-variable rod. On blood agar it forms small transparent colonies and can produce α -hemolysis. This bacterium was first isolated by Robert Koch in 1878 and was proposed by Löffler in 1886 as the causative agent of erysipelas in pigs (Löffler, 1886). In 1909 Rosenbach isolated it from the skin lesions of a man, establishing its role as a human pathogen (Rosenbach, 1909). The disease it produces was called erysipeloid to distinguish it from the previously described erysipelas associated with *S. pyogenes*.

Epidemiology

Erysipeloid is a worldwide zoonosis, mainly related to pigs and fish. Transmission occurs through direct contact with the lesions, so it is a disease related to farmers, butchers, fishermen, veterinarians and other professionals susceptible to occupational exposure.

Clinical manifestations

Erysipeloid, or "Rosenbach's disease", is a cellulitis that is located mainly on the fingers by direct contact with the infected animal. The incubation period is 3–7 days, after which local inflammation with pain or itching occurs. The lesion is defined and reddish or purplish, it spreads over time and may blister. Systemic symptoms such as fever or arthralgia are rare. The main difference with staphylococcal or streptococcal cellulitis is the subacute onset, the absence of suppuration, and severe pain. The condition remits without treatment 3–4 weeks after exposure (Wang et al., 2010).

Systemic infection is very rare; however, cases of bacteremia and even endocarditis due to *E. rhusiopathiae* have been described (Wang et al., 2020).

Diagnosis

Due to the depth of the lesions, biopsies must include the entire dermis, which makes it difficult to take the sample correctly. In the case of suspected *E. rhusiopathiae* endocarditis or bacteremia, blood culture is the best diagnostic technique. Given their slow growth, the cultures should be incubated for at least 7 days (Micaelo et al., 2016).

Therapy

Although data on antibiotic sensitivity are scarce, it is known to have high sensitivity to beta-lactams, clindamycin, quinolones, linezolid, and daptomycin. It is resistant to vancomycin, which is important since it is an antibiotic widely used empirically in Gram-positive bacteremia (Wang et al., 2010).

Prophylaxis

Prophylaxis is focused on exposure, promoting the use of adequate hand hygiene, the use of gloves when handling fish or coming into contact with animals and the correct disinfection of potentially contaminated surfaces. There are veterinary vaccines that can help control swine erysipelas (Opriessnig et al., 2020).

Tropheryma whipplei

Introduction

T. whipplei is a small bacillary actinomycete ($0.25 \times 1.5\text{--}2.5\ \mu\text{m}$) with the ability to invade cells of the immune system such as macrophages of the small intestine, polymorphonuclear cells and intraepithelial lymphocytes, as well as epithelial or muscle cells. It was first described in 1907 by the American physician George H. Whipple, who pointed to it as a possible etiological agent of the disease (Whipple, 1907). It is a very slow-growing bacterium, genetically close to *Nocardia* sp. and other actinomycetes. It is found in wastewater, so it is suspected that infection in humans is acquired through the consumption of contaminated water (Maiwald et al., 1998).

Clinical manifestations

T. whipplei causes a rare disease known as Whipple's disease, considered a sort of intestinal lipodystrophy. It is a systemic infection that affects the intestine, causing diarrhea, abdominal pain and weight loss. In some cases, it can also affect other organs such as the CNS, lungs or heart. As in many infections, the severity of the disease is determined by risk factors such as immunosuppressive treatment.

The digestive picture is characterized by prolonged weight loss, steatorrhea, watery diarrhea, and abdominal cramps. This condition can lead to a syndrome of malabsorption and cachexia (Raoult et al., 2010).

Other symptoms related to Whipple's disease are arthropathies, fever, lymphadenopathy (especially at the mesenteric level), hyperpigmentation of the skin exposed to the sun, hypotension and occult blood in the stool. Regarding cardiac involvement, *T. whipplei* has been associated with endocarditis, aortic or mitral regurgitation, and heart murmurs (Fenollar et al., 2012). The pulmonary picture is associated with chronic non-productive cough, chest pain, and pulmonary hypertension. It is also related to *T. whipplei* with CNS involvement, which can cause myoclonus, nystagmus, dementia and memory disorders (Compain et al., 2013).

Diagnosis

Diagnosis of intestinal infection is usually made by endoscopy, where a mucosal pattern of erythematous areas mixed with pale yellow areas, with whitish plaques, is observed. The characteristic evidence is that the lesions show positive Schiff inclusions. The Schiff technique uses periodic acid Schiff (PAS) as a stain, which turns red in contact with aldehyde groups (Schiff, 1866). The development of a PCR has allowed the rapid and accurate detection of *T. whipplei* from biopsies, although it is normally performed in specialized or reference centers and not routinely in hospitals (El-Abassi et al., 2017).

Diagnosis of cardiac infection is made by histology and PCR of the removed valve.

Therapy

Standard treatment is ceftriaxone (2 g daily) for 2 weeks (up to 4 weeks in cases of CNS infection or endocarditis). It is usually recommended to continue treatment with cotrimoxazole (two daily doses of 160/800 mg) for 1 year. In case of allergy to ceftriaxone, it can be substituted for meropenem. Likewise, cotrimoxazole can be substituted for doxycycline in combination with hydroxychloroquine (Lagier et al., 2014).

Listeria

Introduction

Listeria monocytogenes was first described as a pathogen in 1926 by Murray EGD in an outbreak affecting rabbits (Murray et al., 1926). *Listeria* is an intracellular gram-positive rods widely distributed in the environment, transmitted primarily through contaminated food. The infection is mild and self-limiting in healthy adults but causes severe disease as sepsis or meningitis in people over 50 years of age, neonates and immunocompromised individuals, especially patients with solid or hematological malignancies, solid organ transplant recipients, or patients on chronic immunosuppressive therapy. Although listeriosis has low incidence (0.42 cases/100000 population), this disease is of great public health concern due to outbreaks (European Centre for Disease Prevention and Control, 2020).

Microbiology

The genus *Listeria* consists of a group of gram-positive, non-sporulating, facultative anaerobic rods. They are observed under the microscope singly or in short chains.

Listeria spp. is a saprophytic and ubiquitous bacterium that are isolated from a diversity of environmental sources, including water, soil, a wide variety of foods and the feces of humans and animals. *Listeria* can survive at extreme temperatures or pH making this microorganism a serious threat to food safety in food industry (Vázquez-Boland et al., 2001).

This genus includes six species: *L. monocytogenes*, *L. ivanovii*, *L. seeligeri*, *L. innocua*, *L. welshimeri*, and *L. grayi*. *Listeria monocytogenes* is the main human pathogenic species and will be the focus of this article, although *L. grayi* bacteremia has also been reported in immunocompromised patients. Bacteremia, infection of ventriculo-peritoneal shunts by *L. innocua*. Bacteremia in immunocompromised patients, infections of vascular prosthesis or gastroenteritis due to *L. ivanovii*. And meningitis due to *L. seeligeri* has been reported (Radoshevich and Cossart, 2018).

The characterization of the isolates using multilocus sequence typing (MLST) has divided the species into clonal complexes (CC). They are classified into virulence categories: (1) CC1, CC2, CC4 and CC6 are associated with infections, (2) associated with food and hypovirulent (CC9 and CC121) and (3) the intermediate isolates associated with clinical and food environments (CC5, CC8, CC3, CC37, CC101, CC90, CC7, CC155 and CC77). The whole genome MLST has subdivided CC into clonal types and has revealed the great heterogeneity of isolates in terms of virulence (Chenal-Francisque et al., 2011; Moura et al., 2016; Kwong et al., 2016; Kuch et al., 2018; Lepe, 2020).

Physiopathogenesis and immunity

The main pathogenic factor of *Listeria monocytogenes* is that it is an intracellular pathogen that can grow inside macrophages and epithelial cells. Infection begins after ingestion of contaminated food in high concentrations and its subsequent multiplication in the endothelial cells of the intestine (Vázquez-Boland et al., 2001; Pamer, 2004).

At cell level, the transition from saprophyte to pathogen requires the co-ordinated regulation of bacterial factors that determine pathogenesis and intercellular dissemination. An essential determinant of *L. monocytogenes* pathogenesis is the transcriptional activator PrfA, which activates most of the genes required for cell entry and intracellular parasitism. *L. monocytogenes* induces its own internalization by cells that are normally phagocytic. Its entry into cells is mediated by host surface proteins classified as internalins. Internalin-mediated entry is important for crossing intestinal, blood-brain and foetoplacental barriers. *L. monocytogenes* transits from the gut to the brain or fetus (Nikitas et al., 2011; Bierre et al., 2018; Radoshevich and Cossart, 2018).

The most important factor determining the pathogenesis of *L. monocytogenes* is its beta-hemolysin, listeriolysin O (LLO). Listeriolysin O mediates the breakdown of the phagosomal membrane that forms after phagocytosis of the micro-organism. It probably inserts into an acidifying phagosome preventing vesicle maturation. In addition, it acts as a transposition pore for one or both phospholipases of *L. monocytogenes*, which also contributes to vacuolar lysis. Listeriolysin O synthesis and activity are controlled at multiple levels to ensure that its lytic activity is limited to acidic vacuoles and does not affect the cytosol. Mutations in listeriolysin O that influence its synthesis, cytosolic half-life or pH optimum reduce premature toxicity in infected cells (Nikitas et al., 2011; Bierre et al., 2018; Radoshevich and Cossart, 2018).

Once in the cytosol, *L. monocytogenes* proliferates quickly. One of the PrfA-regulated genes encodes the synthesis of a hexose-phosphate transporter that facilitates the proliferation of cytosolic bacteria on phosphorylated glucose derivatives originating from the host. Then in the cytosol it produces ACTA, another PrfA-regulated surface protein that mediates the nucleation of host actin filaments to propel bacteria into and between cells. ActA mimics host proteins by promoting the actin nucleation properties of the Arp2/3 complex. Consequently, *L. monocytogenes* enters the cytosol of almost any cell (Nikitas et al., 2011; Bierre et al., 2018; Radoshevich and Cossart, 2018).

After the process of endocytosis and activation, they can be ingested by macrophages and reach the liver and spleen, leading to the spread of infection. By multiplying in macrophages, they prevent them from being eliminated by antibodies, so individuals with impaired cell-mediated immunity are more susceptible to this infection while humoral immunity is of no importance.

The incubation period varies from 3 to 70 days, with a median of 21 days (Coulet et al., 2013). It is variable depending on the clinical manifestation of the disease: for gastroenteritis cases the median incubation period is 24 h, for bacteremia is 1–12 days, for neurolisteriosis 1–14 days and in cases related to pregnancy 17–67 days (Lepe, 2020).

Iron overload is a virulence factor as the siderophores of *L. monocytogenes* enable it to take up iron from transferrin, hence iron-containing culture media favor its cultivation.

Epidemiology

Listeriosis is a relatively uncommon but severe invasive infection caused by *Listeria monocytogenes*. It is an environmental bacteria, which can inhabit water, soil and plants. It can be present in the human microbiota, being present in 5% of healthy adults in their feces (Swaminathan and Gerner-Smidt, 2007).

Listeria monocytogenes infection is uncommon in immunocompetent individuals and may present with fever or self-limiting gastrointestinal infection. In pregnant women, neonates, elderly and immunocompromised individuals, may cause severe infections such as bacteremia, meningoencephalitis or maternal-fetal listeriosis.

The most frequent cases of human listeriosis occur through ingestion of contaminated food (unsanitized (soft) milk and cheeses, prepared foods such as paté, sliced meat products, contaminated vegetables or smoked fish products), or in the case of newborns through transplacental transmission, which is the only case of inter-human transmission.

Severe clinical cases occur in children younger than 30 days or adults older than 65 years, in pregnant women and in immunocompromised populations such as recipients of solid organ transplants, solid or hematological malignancies, immunosuppressed or patients treated with chronic corticosteroids.

Thirteen serotypes of *Listeria monocytogenes* and four distinct lineages that are related to the serotypes have been identified. The serotypes most frequently identified in food and clinical samples are 1/2a, 1/2b, 1/2c and 4b (96% of isolates). Most outbreaks are caused by 4b. Pulsed field gel electrophoresis (PFGE) or ribotyping techniques can be used to detect outbreaks for epidemiological purposes (Radoshevich and Cossart, 2018).

Despite being sporadic, listeriosis has caused outbreaks worldwide. The largest outbreak to date has occurred in South Africa from ready-to-eat processed meat product. A total of 1060 associated cases were reported, with an estimated case fatality from or with the infection of 30% (Thomas et al., 2020; European Centre for Disease Prevention and Control, 2020).

Listeriosis incidence in Europe

From 2013 to 2017, between 1905 and 2527 cases of listeriosis were reported to the European Surveillance System (TESSy) annually in 30 EU countries. Of the cases reported in this period, Germany, France and Spain accounted for 26%, 17% and 10%, respectively. Severe *L. monocytogenes* infections were more common in men (54%) and in people over 65 years of age (65%). The majority of cases (98%) were of autochthonous origin.

According to surveillance data in Europe coordinated by the ECDC, the incidence rate in the European Union in 2017 was 0.42 cases per 100,000 population and the highest rate was detected among people over 64 years (1.7 cases per 100,000 population) (European Centre for Disease Prevention and Control, 2020).

In Spain since the 2015 Ministerial Order, listeriosis has been included among the diseases under compulsory surveillance in Spain. Previously, it was reported to the National Epidemiological Surveillance Network (RENAVE) through the Microbiological Information System (SIM) on a voluntary basis.

In the period 2015 to 2018, fifteen autonomous communities and cities notified 1369 confirmed cases to the RENAVE, so that around 300–400 cases are being recorded annually. In Andalusia, an average of 65 cases per year have been reported. In 2018, 432 cases were reported. Its usual presentation is in the form of sporadic cases or small intra-familial outbreaks. Specifically, there are eight outbreaks reported since 2015, with two to three cases per outbreak, and they are usually clusters due to vertical, mother-to-newborn transmission (six outbreaks) or small family foodborne outbreaks (two outbreaks). The average age of cases reported to the Surveillance Network during these years is around 65–70 years and there have been 124 deaths, representing a case fatality rate of around 9%. In general, case fatality increases with age (Centro Nacional de Epidemiología, n.d.).

The most significant outbreak of listeriosis recorded in Spain is in Andalusia in August 2019, and the only one that has been associated with such widely distributed commercial products, specifically in larded pork (Lepe, 2020).

Recommendations on Listeriosis prevention

Cooking food at temperatures above 65 °C kills bacteria. However, *Listeria monocytogenes* can contaminate food after processing (e.g., contamination can occur after food is cooked but before packaging). Unlike many other foodborne bacteria, *Listeria* tolerates salty environments and can even multiply at cold temperatures between +2 °C and 4 °C. To prevent listeriosis it is important to follow good manufacturing practices, good hygienic practices and effective temperature control throughout the food production, distribution and storage chain, including in the home. The resistance of this bacterium, together with high mortality rates in humans, makes safe food handling paramount to ensure public health (Ministerio de Sanidad, n.d.).

In pregnant women, they are reminded of the need to take certain additional hygiene measures and to avoid consumption of certain foods in order to prevent risks which, although rare, may have negative consequences for the fetus or the pregnant woman.

Clinical manifestations

Listeria monocytogenes can cause two forms of listeriosis, non-invasive gastrointestinal and invasive listeriosis.

Listeria infections cause a variety of clinical syndromes, the most common are meningitis and septicemia, especially in immunocompromised patients.

Gastroenteritis: Occurs within 48 h of ingestion of a significant inoculum of bacteria in contaminated foods such as milk, deli meats and salads. Clinical manifestations are fever, diarrhea, headache and general symptoms. Isolated gastrointestinal disease does not require antibiotic treatment (Ooi and Lorber, 2005).

Bacteremia: *L. monocytogenes* septicemia is manifested by fever, chills, myalgia and arthralgia, indistinguishable from bacteremia caused by other bacteria. Meningeal symptoms, neurological or focal data or changes in mental status suggest the diagnosis. In the MONALISA study where patients with invasive listeriosis between 2009 and 2013 were included, of which 427 were primary bacteremia. Mortality was 46% at 90 days (Charlier et al., 2017).

Infection during pregnancy and neonatal infection: Listeriosis in pregnancy causes a serious threat to the fetus that may result in miscarriage.

Listeriosis occurs up to 20 times more frequently in pregnant women than in the general population (Mulonakis et al., 2002). Listeriosis occurs mainly during the third trimester and most of the time asymptotically or with minor symptoms, but the effects on the fetus are greater the less advanced the stage of gestation and can cause miscarriage or death in up to 20% of cases (Silk et al., 2012).

The usual clinical presentation is an acute or subacute non-specific febrile illness with myalgias, arthralgias, dorsalgia and headache. Pregnant women with listeriosis often suffer from bacteremia. Central nervous system involvement is rare. Even without treatment, the prognosis for the mother is very good but not for the fetus. Up to 2/3 of live births to women who have had listeriosis during pregnancy may develop neonatal listeriosis, hence the importance of early diagnosis (Craig et al., 2019).

Infection in the fetus can be via the transplacental route or by passage through the birth canal. If infection occurs in utero, infantiseptic granulomatosis, a form of listeriosis characterized by microabscesses and disseminated granulomas mainly in the liver and spleen, can occur, with a mortality rate of 50% (Lamont et al., 2011; Wadhwa Desai and Smith, 2017).

Neonatal listeriosis can be early-onset (less than 7 days of life) or late-onset (more than 7 days). In early-onset listeriosis, the neonate may present with early-onset sepsis often associated with respiratory distress or pneumonia, skin lesions with or without conjunctivitis. In late onset, they develop sepsis and even meningitis. Many of these cases involve full-term infants who become infected while passing through the birth canal and whose mothers remained asymptomatic during pregnancy. Mortality is around 25% in these cases.

The prospective Monalisa study included 107 infections in pregnant women. The most common diagnosis was fever with obstetric symptoms (contractions, labor or fetal loss). In 83% of the infections there were serious consequences for the fetus: fetal death (24%), premature delivery (45%) (Charlier et al., 2017).

Central nervous system infections: Invasive *Listeria monocytogenes* infection causes CNS involvement relatively frequently due to the tropism of the bacterium for the meninges and brain parenchyma, especially the brainstem, and mortality is high and neurological sequela can affect more than 60% of survivors (De Valk et al., 2005). *L. monocytogenes* causes approximately 5–10% of cases of adult out-of-hospital bacterial meningitis in the United States (Harrison). The presentation is subacute and nuchal rigidity and meningeal signs are less common. Photophobia is rare. Cerebrospinal fluid chemistries in listerogenic meningitis most often show leukocyte counts in the range of 100–5000/ μ L, rarely higher; 75% of patients have leukocyte counts below 1000/ μ L, with neutrophil predominance more modest than in other bacterial meningitis. Low glucose concentrations and the observation of typical gram-positive bacilli on Gram stain are found in about 30–40% of cases (Hohmann and Portnoy, 2020).

L. monocytogenes can directly invade the brain parenchyma and produce cerebritis or focal abscess (Hohmann and Portnoy, 2020). In these cases the predominant clinical presentation is altered consciousness or cognitive dysfunction and may mimic Herpes encephalitis. Blood cultures are often positive and concomitant meningitis may develop (Pelegri n et al., 2014).

Other focal infections: Focal infections of visceral organs, eyes, pleural, peritoneal and pericardial spaces, bones and joints have been reported in low percentages (about 3%) (Bartolom   et al., 2005; Benjelloum et al., 2011; Charlier et al., 2012; Morgand et al., 2018; Shoai-Tehrani et al., 2019; Lepe, 2020).

Diagnosis

A microbiological diagnosis is based on conventional staining and culture techniques of samples taken from a sterile location (blood, cerebrospinal fluid or less frequently pleural, articular fluid, pericardial, etc.). The study of other samples as placenta, amniotic fluid may be indicated within the first 48 h after delivery. The samples should be submitted to the laboratory as soon as possible and if not, they can be stored at 4  C for a maximum of 48 h.

Listeria monocytogenes is a tiny, Gram-positive rod exhibiting tumbling motility at room temperature. The sensitivity of gram staining in cerebrospinal fluid is low but Multiplex PCR assay can be performed in patients with suspected central nervous system infections to confirm the diagnosis (Caillaux et al., 2020). It is easily isolated on enriched media such as blood agar or chocolate, is a gram positive catalase positive and oxidase negative rod, which produces hemolysis and grows readily on blood agar. The presence of a small zone of beta-hemolysis on blood agar. *L. monocytogenes* is CAMP test positive. Its growth is optimal at 37  C but it also grows at low temperatures (Anand et al., 2016). It is resistant to low pH and high salt environments making it an important pathogen in the food industry. For identification to species level, Maldi-Tof is currently used. For epidemiological studies, typing techniques such as PFGE or ribotyping are used.

Treatment

In listeriosis, recommended treatment is based on the result of antibiotic susceptibility testing (Mart  nez-Macias et al., 2012). Treatment is ampicillin 200–300 mg/kg/day. Consideration should be given to the association with gentamicin 5–7 g/kg 7/day (during the first week) in case of central nervous system infection, endocarditis or immunosuppression (Lorber 1997).

Associations of ampicillin with ceftriaxone and ampicillin with daptomycin have been shown to be synergistic in vitro and in animal models of *Listeria* endocarditis (Radoshevich and Cossart, 2018; Lepe et al., 2019; Mensa and Soriano, 2021).

The association of ampicillin with co-trimoxazole (trimethoprim 20 mg/kg/day in 3–4 doses) is at least as effective as the association of ampicillin with gentamicin and may be more appropriate if the infection is localized in the central nervous system or the risk of nephrotoxicity is high. Treatment is maintained for 2 weeks for isolated bacteremia, 3 weeks for meningitis, 4–6 weeks for endocarditis and more than 6 weeks for rhombencephalitis, brain abscesses or neurological focality (likely microabscesses). Alternatives are co-trimoxazole/TMP 20 mg/kg/day in 3–4 doses alone or in combination with rifampicin in case of central nervous system infection. Clarithromycin or doxycycline in isolated bacteremia. The following antibiotics: rifampicin, moxifloxacin, levofloxacin, meropenem and linezolid are active against *Listeria* but clinical experience with their use is limited. The use of linezolid and/or rifampicin may be considered in the treatment of brain abscess. Vancomycin is active, but clinical efficacy is irregular. Cephalosporins are not active against *Listeria* (Radoshevich and Cossart; Lepe et al., 2019; Mensa and Soriano, 2021).

In immunosuppressed, pregnant and over 65-year-old people, consider amoxicillin for 7 days in situations of invasive infection as a complication of gastrointestinal listeriosis. In the recent outbreak in 2019 in Andalusia used this recommendation until the blood culture result was known (Lepe, 2020).

Antimicrobial resistance

Listeria species are intrinsically resistant to several antibiotics, including first-generation quinolones, broad-spectrum cephalosporins, monobactams and fosfomycin. The mechanism associated with cephalosporin resistance in *Listeria* spp. is complex and is thought to be secondary to unique penicillin binding protein in the cytoplasmic membrane, which is the primary target for other beta-lactams but does not bind well to cephalosporins (Anand et al., 2016).

Trimethoprim resistance may not be detected if the anti-biogram is performed with co-trimoxazole discs. Recognizing this, is clinically important, as they are commonly employed to empirically treat sepsis and meningitis of unknown etiology (Anand et al., 2016). The mortality rate is high, reflecting the combination of an immunocompromised host and an often delayed diagnosis (Schlech, 2019).

Erysipelothrix

Introduction

Erysipelothrix species are ubiquitous in nature and have been isolated from a variety of animals species.

The genus *Erysipelothrix* is composed of at least five species, *E. rhusiopathiae*, *E. tonsillarum*, *E. inopinata*, *E. larvae* and *E. piscicarius* sp. nov.

E. rhusiopathiae is a facultative anaerobic non-spore-forming Gram-positive rod. It is a zoonotic pathogen causing human disease rarely. It occurs mainly in individuals with exposure to contaminated animal and fish products (Rihana et al., 2018). There are three well-defined manifestations in humans: a localized cellulitic form known as erysipeloid of Rosenbach, a diffuse cutaneous form, and a septicemic form that is associated with endocarditis (Brooke and Riley, 1999; Lorenz et al., 2018). Other rare manifestations in humans are abscess formation, septic arthritis, and osteomyelitis (Reboli and Farrar, 1989; Brooke and Riley, 1999; Principe et al., 2016).

The term erysipeloid was introduced by Rosenbach, who isolated it from a localized lesion in a man and established its human pathogenicity to avoid confusion with typical bacterial erysipelas caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, less so by group B, C or G Streptococci.

Microbiology

Surface swabs are not useful for isolation of *E. rhusiopathiae* from cutaneous lesions since the organisms reside deep in the subdermal layer. Biopsy specimens are optimal for isolation of the organism. In bloodstream infections, can be recovered from standard blood cultures.

Gram staining shows short, thin, straight or slightly curved gram-positive bacilli, sometimes with a tendency to form long filaments. After growth for 24 h at 37 °C on standard culture media such as blood agar, the colonies are small and clear. These bacteria are catalase-negative, oxidase-negative and capable of producing SH2. The microbiological differential diagnosis should be made with other gram-positive bacilli such as *Listeria monocytogenes* and *Corynebacterium* species.

The introduction of mass spectrometry (MALDI-TOF) in clinical microbiology laboratory has improved identification of microorganism at species level.

This approach could allow to reduce the duration of empirical treatment and improve the appropriate therapy for infections caused by fastidious pathogen.

Epidemiology

It is a globally distributed microorganism, commensal or pathogenic to many animals, including mammals, birds and fish. The main reservoir is the domestic pig. It is able to live for prolonged periods in soil. Zoonotic infection is the most important route of transmission of the bacterium to humans. Transmission from animals to humans occurs by direct skin contact (abrasions or wounds), so most human cases are related to occupational exposure, veterinarians, farmers, slaughterhouse workers, etc.

In the absence of occupational exposures, risk factors for invasive infection include immunosuppressing condition such as diabetes mellitus, chronic kidney disease and treatment with high-dose steroids. In patients with endocarditis, excessive alcohol use, in addition to underlying heart conditions has also been identified as a risk factor (Jean et al., 2019).

No inter-human transmission has been reported. *E. rhusiopathiae* cannot resist temperatures above 55 °C, but can resist salting and smoking of food.

Clinical manifestations

Infections can manifest in one of the following three forms:

- Erysipeloid: This is the localized cutaneous lesion that manifests as subacute cellulitis. It usually occurs on the upper limbs after cuts or abrasions. It is the most common presentation in humans. The incubation period is 2–7 days. The clinical presentation is characterized by severe pain with edema. The skin is reddish-violet in color and appears bordered and raised. Vesicles may appear. Adjacent joints may also be inflamed. Is typically limited to the fingers or hand.
- Diffuse cutaneous infection: an extensive area of rash may be seen from the initial lesion at the site of inoculation and/or the appearance in remote areas of erysipeloid skin lesions with a typical rhomboidal appearance. General symptoms are frequent and include fever and severe arthralgias. Blood cultures are usually negative.

These patients usually have the same exposures as those with erysipeloid. However eating contaminated seafood or undercooked has been associated with this infection form.

Bacteremia, whether or not associated with endocarditis: Rare and in most cases associated with endocarditis on native valves (Artz et al., 2001; Nielsen et al., 2018). Complications include heart failure, myocardial abscess, aortic valve perforation, meningitis and glomerulonephritis. Brain abscess, osteomyelitis, chronic arthritis and primary bacteremia are rarely reported in immunocompromised patients. Chronic liver disease is an important predisposing factor, more than one-third of patients with systemic infection are alcoholics (Schuster et al., 1993; Balkhair et al., 2019).

Uncommon forms of infection due to *E. rhusiopathiae* include brain abscess, endophthalmitis, meningitis, psoas abscess, intra-abdominal abscess, prosthetic joint infection, tenosynovitis, pneumonia, epidural and paravertebral abscesses, periosteal dialysis-related peritonitis with bacteremia, necrotizing fasciitis and osteomyelitis (Kim et al., 2007; Elvy et al., 2008; Hocqueloux et al., 2010; Feasi et al., 2010; Meric and Keceli Ozcan, 2012; Groeschel et al., 2019).

Diagnosis

Identification of *Erysipelothrix* species can be difficult. They can have an uneven Gram stain appearance and appear as gram negative. Colonies are alpha-hemolytic and can resemble streptococci or enterococci. Similar to enterococci is also positive for pyrrolidonyl aminopeptidase (PYR) activity, but *Erysipelothrix* produce hydrogen sulfide (H₂S) on TSI agar and not enterococci. Positive catalase reactions differentiate *Corynebacterium* spp. and *Listeria* spp. from *Erysipelothrix* spp. which are negative for catalase, oxidase, indole, methyl red, Voges-proskauer and hydrolysis of esculin or urea. *Lactobacillus* spp. are catalase negative, slender Gram positive bacilli associated with endocarditis and bloodstream infection and can be vancomycin resistant as *Erysipelothrix* but *Lactobacillus* are negative for H₂S production (Jean et al., 2019).

Differential diagnosis

Clinically, the classic erysipeloid lesion is similar to staphylococcal or streptococcal cellulitis. In the differential diagnosis, a history of occupational exposure, lesions on the hands, absence of suppuration, subacute course, red-violet skin discoloration and pain apparently disproportionate to the extent of the lesion are typical of *E. rhusiopathiae* infection.

E. rhusiopathiae may be underdiagnosed and undertreated. It's important a good history including occupational exposure and be vigilant to add coverage for this uncommon fastidious organism.

Treatment

E. rhusiopathiae are generally susceptible to penicillin, cephalosporins, fluoroquinolones and carbapenems (Venditti et al., 1990).

Cellulitis of limited extent and without systemic damage can be treated with oral amoxicillin or ciprofloxacin.

More severe infection is treated with penicillin G sodium 12–20 × 10⁶ IU/day iv. In endocarditis treatment should be prolonged by 4–6 weeks (2 weeks iv and 2–4 weeks oral) (Mensa and Soriano, 2021).

Antimicrobial resistance

It is intrinsically resistant to co-trimoxazole, aminoglycosides and glycopeptides.

Patients with osteomyelitis usually receive empiric treatment with vancomycin and in abscesses is common to choose trimethoprim-sulfamethoxazole so this should be taken into consideration when *E. rhusiopathiae* is suspected (Lorenz et al., 2018).

Introduction

Corinebacteriae are immobile gram-positive bacilli, mostly catalase positive, also called “diphteromorphs or corineform” bacilli because they possess many strains of similar morphology. Called “diphtheromorphs” due to the possession of a morphology like *C. diphtheriae*, this being the oldest known pathogen of the genus and causal agent of diphtheria and “corineforms” by its form of mace or cane word whose etymology derives from the ancient Greek word “coryne” (Bernard, 2005; Funke and Bernard, 2007).

They have traditionally been considered as harmless saprophytic bacteria and their microbiological finding has been considered as contamination in sampling or as colonization with no clinical significance to the patient, however, their pathogenicity is believed to be underestimated in previous years and begins to take on importance, strengthening its role as a producer of certain opportunistic infections and in immunocompromised or prosthetic carriers. This has helped advance its more accurate and simple identification through the implementation in laboratories of more advanced molecular diagnostic methods and bacterial identification based on mass spectrometry, specifically in the MALDI-TOF MS.

The main pathogen of this genus and best known remains *C. diphtheriae*, a cause of diphtheria, a serious epidemic infectious disease that in developed countries has virtually disappeared thanks to immunization through the vaccine containing diphtheric toxoid and which is included in universal vaccine schedules (Wagner et al., 2012). In this article we will talk about the species of the genus *Corynebacterium* of medically relevant interest.

Microbiology

The genus *Corynebacterium* has more than 88 validated species that are increasing over the years, characterized by their high heterogeneity. It includes species that are of medical relevance because they produce rare infections in humans, although they do not always act as opportunistic pathogens. They are also important in veterinary medicine, where they are sometimes producers of zoonoses and also have uses in biotechnology (Bernard, 2012; Soares et al., 2013; Eikmanns and Blombach, 2014). They are bacteria that are present in the human microbiome but also in the environment, in water, in food, on the surface of inert materials.

They come from the bacterial family Corynebacteriaceae belonging to the phylum Actinobacteria. In this family the two genera *Corynebacterium* and *Turicella* (Busse, 2012) are closely related, their difference being that in the former the presence of mycolic acids

is detected in their cell wall except for three species (*C. amycolatum*, *C. atypicum* and *C. kroppenstedtii*) and absence of tuberculostearic acid (TBSA) except for some species where it is also present (*C. appendicis*, *C. bovis*, *C. confusum*, *C. kroppenstedtii*, some strains of *C. minutissimum*, *C. mucifaciens*, *C. tuberculoestearicum*, *C. urealyticum*) (Funke and Bernard, 2011) and *C. ureicelerivorans* (Yassin, 2007). In the genus *Turicella*, TBSA is always present but never mycolic acids.

In the last 30 years there have been multiple changes in the number of species assigned to this group of *Corynebacterium*. Many species have been included thanks to the improvement in identification techniques, even in some cases, all those species whose genetic characteristics were incompatible have been eliminated and have subsequently been included in other genus.

Corynebacteria of interest in human pathology are part of the normal microbiota of the skin, upper respiratory tract, digestive and genitourinary tract such as *C. jeikeium* and *C. amycolatum*. They are Gram-positive, aerobic or facultative anaerobic bacilli because they possess an enzyme called catalase which allows them to grow properly in the presence of oxygen. They are non-motile and non-sporulating.

Most corynebacteria grow well in the usual culture media that are available in microbiology laboratories. They multiply adequately by incubation at a temperature of 37 °C, with the exception of some strains that benefit from the addition of 5% CO₂, or a temperature of 30 °C or culture in media enriched with fosfomycin or 0.1–1% Tween 80 (Bernard, 2012).

Identification methods

There are three main methods of identification:

Method based on phenotype: Through the observation of the morphology of colonies after 24 or 48 h of incubation in those of slow growth. Using Gram staining, oxidase and catalase reactions and checking if the isolate has lipophilic or non-lipophilic character. In addition, the strains of present a wide variety of different metabolic processes.

According to this there is a useful way to classify corinebacteria based on their lipophilic or non-lipophilic character. These different lipophilic and non-lipophilic species, in turn, can behave as fermenters and non-fermenters of sugars (Funke et al., 1997).

	Fermentative	Oxidative
No Lipophilia	<i>C. amycolatum</i> , <i>C. argentoratense</i> , <i>C. auricanis</i> , <i>C. aurimucosum</i> , <i>C. canis</i> , <i>C. confusum</i> , <i>C. coyleae</i> , <i>C. diphtheriae</i> (biotipos <i>gravis</i> , <i>mitis intermedius y belfanti</i>), <i>C. durum</i> , <i>C. falsenii</i> , <i>C. flavescens</i> , <i>C. freneyi</i> , <i>C. glucuronolyticum</i> , <i>C. hansenii</i> , <i>C. imitans</i> , <i>C. matruchotii</i> , <i>C. minutissimum</i> , <i>C. pseudotuberculosis</i> , <i>C. riegliei</i> , <i>C. simulans</i> , <i>C. striatum</i> , <i>C. sundsvallense</i> , <i>C. thomsseni</i> , <i>C. timonense</i> , <i>C. tuscaniae</i> , <i>C. ulcerans</i> , <i>C. xerosis</i>	<i>C. afermentans</i> subsp. <i>Afermentans</i> , <i>C. auris</i> , <i>C. massiliense</i> , <i>C. mucifaciens</i> , <i>C. propinquum</i> , <i>C. pseudodiphtheriticum</i>
Lipophilia	<i>C. appendicis</i> , <i>C. accolens</i> , CDC grupo F1, CDC grupo G, <i>C. diphtheriae</i> biotipo <i>intermedius</i> , <i>C. kroppenstedtii</i> , <i>C. macginleyi</i> , <i>C. resistens</i> , <i>C. tuberculoestearicum</i> , <i>C. ureicelerivorans</i>	<i>C. afermentans</i> subsp. <i>Lipophilum</i> , <i>C. bovis</i> , <i>C. jeikeium</i> , <i>C. lipophiloflavum</i> <i>C. urealyticum</i>

Corynebacteria with relevance in human infections. Classification according to your oxidative or fermentative metabolism and lipophilia.

The phenotypic methods have as a limitation that they do not correctly identify 30% of the strains. The number of substrates to test with each strain is limited and are difficult to apply in strains of difficult growth. The results are sometimes obtained in days and the databases for establishing identification after the completion of the tests are updated infrequently.

Method based on the sequence of a gene: if we sequence the 16S rRNA gene we will have a good starting point to be able to discriminate between different species of the genus *Corynebacterium* and will allow in most cases its definitive identification. In exceptional cases where typing of the strain is not possible, we can resort to sequencing a secondary gene, such as the *rpoB* gene (Khamis et al., 2004).

Methods based on the use of MALDI-TOF: This bacterial identification tool is becoming a common resource in microbiology laboratories. It has an affordable cost and does not require to be carried out by highly trained technical personnel. A mass spectrometer detects proteins ionized and released from bacteria thanks to a laser. A pattern is then generated that is compared in a database giving a degree of coincidence (Konrad et al., 2010).

Virulence factors

Species of the genus *Corynebacterium* have different virulence factors:

Adhesion mechanisms: They can adhere to the eukaryotic cells of the host expressing molecules such as lipoglycans that interact with human respiratory cells. In addition, they have another type of adhesins of protein character anchored in the surface of the cell wall like pilis and fimbrias that act by means of mechanisms mediated by sortases.

Toxicity: some strains such as *C. diphtheriae* after being infected by lysogenic bacteriophages that hold the *tox* gene and after a conversion mechanism, can produce diphtheria exotoxin. Another toxin is phospholipase D, which also facilitates the spread in host tissues.

Intracellular survival: It can present lipids on the surface that allow them to alter the intracellular medium of macrophages and be able to live inside, preventing their elimination and causing cell death (Oliveira et al., 2017).

Mechanisms of resistance to antibiotics

In the evolution of antibiotic resistance of the genus *Corynebacterium* most studies conclude that extrachromosomal genetic elements are involved in resistance gene transfer. Horizontal gene transmission plays an important role in their pathogenicity. Antibiotic resistance genes are localized in large plasmids, for example, the pTP10 plasmid is responsible for the resistance to chloramphenicol, tetracycline, streptomycin, and erythromycin described in *Corynebacterium xerosis* (Oliveira et al., 2017).

Many species such as *C. striatum*, *C. pseudodiphtheriticum*, *C. jeikeium* and *C. coyleae* (Fernández-Natal et al., 2008) are resistant to macrolides because they possess ermX genes. For this reason, erythromycin, which had traditionally been the treatment of choice, has ceased to be used unless the sensitivity report of the laboratory confirms its sensitivity. It has also been linked to resistance to clindamycin, and trimethoprim-sulfamethoxazole.

Another example is the existence of multidrug-resistant strains, such as *C. amycolatum*, one of the most common strains of corynebacteria. This property is defined by the existence of resistance to three or more groups of antibiotics commonly used in the treatment of infection such as beta-lactam, aminoglycosides, macrolides, MLSB group and quinolones. The presence of mutations in the gyrA gene is related to resistance to treatment with quinolones (Ortiz-Perez et al., 2010).

Main species of *Corynebacterium*: Pathogenesis, clinical features, diagnosis and treatment

In the table below, we can visualize the most important pathogenic species of *Corynebacterium* along with the clinical manifestations attributed to them (Oliveira et al., 2017).

Taxonomy	Pathogenesis
<i>C. accolens</i> (Ang and Brown, 2007; Wong et al., 2010)	Pelvic Osteomyelitis; Granulomatous Mastitis, endocarditis, keratoconjunctivitis, infection of wounds and soft parts, otitis media, sinusitis, meningitis, bacteremia
<i>C. afermentans</i> subsp <i>afermentans</i>	Bacteremia
<i>C. afermentans</i> subsp <i>lipophilum</i>	Endocarditis. Liver and lung abscesses, lung abscesses and empyema in aids.
<i>C. amycolatum</i>	Endocarditis, sepsis. Bacteremia in immunocompromised patients, osteoarticular infections. Meningitis. Urinary tract infection. Wound infection. Otitis media. Prepuberal vaginitis. Breast abscess.
<i>C. argentoratense</i> (Riegel et al., 1995)	Tonsillitis
<i>C. aurimucosum</i> (Lo et al., 2015)	Urinary tract infection. Bacteremia. Osteoarticular infections.
<i>C. auris</i>	Otitis media in children
<i>C. auriscanis</i> (Collins et al., 1999)	Dog bite infection
<i>C. bovis</i> (Burr et al., 2012)	Hyperkeratosis, mastitis. CNS infection, Endocarditis. Chronic Otitis media infection of coma ulcers of coma joint prosthesis of ventricle-jugular bypass and glomerulonephritis. Bacteremia. Eye infection.
<i>C. camporealensis</i>	Mastitis
<i>C. canis</i>	Dog bite
<i>C. confusum</i>	Abscesses. Bacteremia
<i>C. coyleae</i>	Bacteremia. Urinary tract infection, soft parts infection, pancreatic abscess.
<i>C. diphtheriae</i>	Diphtheria

<i>C. ureicelerivorans</i>	Septicemia. Ascites.
<i>C. xerosis</i>	Bacteremia. Neonatal sepsis. Endocarditis. Foreign material infections. Brain abscess. Meningitis. Arthritis. Spinal osteomyelitis. Pneumonia. Mediastinitis. Intra-abdominal and surgical wound infection.

This table of the genus *Corynebacterium* has been modified from references Bernard (2005), Bernard and Funke (2012), Funke and Bernard (2011), Wattam et al. (2014), Mensa et al. (2021).

We detail below some of the most important species of corinebacteria with human clinical relevance, specifying which disease is caused by the infection and what will be the appropriate antibiotic regimen. Treatment for the different species of *Corynebacterium* is obtained by antibiotic sensitivity tests according to the criteria of the reference laboratories EUCAST and CLSI.

***Corynebacterium diphtheriae*, *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*: A disease called diphtheria**

Diphtheria is an epidemic acute bacterial disease of worldwide distribution rare in developed countries due to universal vaccination against the disease. The disease mainly affects the upper respiratory tract such as tonsils, nasal mucosa, larynx and pharynx. Less often it can affect the skin, eye conjunctiva and vagina.

The species *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis* form the group *C. diphtheriae*. These three species share different characteristics being the most important the possibility of being able to host the bacteriophage that induces the generation of the diphtheria exotoxin and/or the production of phospholipase D (Belchior et al., 2009).

Man is the only reservoir of *C. diphtheriae* and animals are the reservoir of *Corynebacterium ulcerans* like sheep and to a lesser extent domestic animals. In poor countries, cases of diphtheria continue to appear because they do not have adequate immunization in the absence of well-structured vaccination plans for the population. The development of European active immunization programs against diphtheria has been successful and is now an uncommon disease in our midst.

Other infections caused by *C. diphtheriae* produced by strains that do not produce diphtheria exotoxin are arthritis, endocarditis, sepsis and osteomyelitis mainly in parenteral drug users.

Etiology

Diphtheria is produced by bacteria of the genus *Corynebacterium*. The disease occurs when the subject becomes infected with a toxigenic strain of *C. diphtheriae* and is less frequently caused by *C. ulcerans*. The species *Corynebacterium pseudotuberculosis* is usually the etiological agent of granulomatous lymphadenitis located in subjects who are in contact with sheep or have taken unsterilized milk, but there are also strains capable of producing toxin.

There are four biotypes of *C. diphtheriae*: *gravis*, *mitis*, *intermedius* and *belfanti*. Everyone can carry the gene that encodes the diphtheria toxin.

Epidemiology

It is a disease that mainly affects young children but the good vaccination coverage in this age group has led to cases being observed in adult individuals.

Sixty-two cases of diphtheria confirmed by reference laboratories were reported in Europe in 2018. Twenty-nine cases due to *Corynebacterium diphtheriae* and 33 cases caused by *Corynebacterium ulcerans*. The overall reporting rate was 0.01 cases per 100,000 population.

Diphtheria caused by *C. diphtheriae* was reported by nine countries. Most cases of diphtheria due to *C. diphtheriae* were imported. Among the affected countries, Latvia reported the highest number of autochthonous cases followed by France (European Centre for Disease Prevention and Control, 2021; Centers for Diseases Control and Prevention, 2018).

Since 1904 diphtheria is a notifiable disease in Spain. The skin form of diphtheria began to be declared in 2014. Confirmation of a case of diphtheria requires isolation in a clinical sample of a strain of *C. diphtheriae*, *C. ulcerans* or *C. pseudotuberculosis* capable of producing toxin (National Epidemiological Surveillance Network (RENAVE), 2019).

The last two cases reported during the twentieth century in Spain were recorded in 1986. No cases of respiratory diphtheria were reported over a period of 28 years. From 2014 to 2019, eight cases of diphtheria have been reported, three of them of imported origin from an endemic area. In two cases the clinic was respiratory, in two others the disease was located in the cutaneous and the other case the clinical manifestation was respiratory and cutaneous. In the reference laboratory, *C. diphtheriae* and *C. ulcerans* were identified as etiologic diphtheria agents and were not associated with a single clinical presentation (National Epidemiological Surveillance Network (RENAVE), 2019).

Diphtheria is a life-threatening infectious clinical picture. The lethality if the disease is not treated is 5–10%, being 20% in children under 5 years.

Pathogenesis and clinical manifestations

The disease is produced by toxigenic strains. For a strain to produce toxin it must have been infected by a lysogenic phage containing the diphtheria toxin gene which is type A/B.

Transmission of *C. diphtheriae* is from person to person by air or by close physical contact with the patient or asymptomatic carrier. When the microorganism reaches the susceptible subject, it begins its multiplication and after 2–7 days of incubation period begins to excrete the toxin that is its main virulence factor and justifies the appearance of symptoms at a distance from the focus of respiratory infection, such as myocarditis, renal failure, neurological involvement, etc.

The clinic is characterized by the appearance of characteristic lesions located in the mucous membranes have the appearance of pseudomembranes and that are in the respiratory mucosa of the upper respiratory tract. It usually starts in tonsils and thickens, acquiring a grayish color. The lesion, called diphtheria membrane, is drawing a kind of mold of pharynx and trachea that ends up compromising the adequate respiratory function of the patient. When trying to separate it bleeds easily so that the necrotic cells together with inflammation and exudate favors the own elaboration of more toxin. Symptoms such as fever, chills, characteristic enlargement of the nodes of the neck, producing an appearance of bull's neck, sore throat and hoarseness, general malaise, runny nose and difficulty breathing, which can be aggravated and require orotracheal intubation, are accompanied. At 10–14 days due to the spread of the toxin, cardiac complications such as myocarditis, renal complications appear and between 1 and 4 weeks later peripheral neuritis may appear. It is a life-threatening disease (American Academy of Pediatrics, 2018).

The transmission of *Corynebacterium ulcerans* is through contact with animals including domestic animals or the consumption of unpasteurized milk. Vesicular inflammatory lesions appear that evolve into a chronic grayish ulcer with defined edges.

The individual's vulnerability to diphtheria and its severity depends on its ability to generate toxins, the infective dose and the immune status of the person—(National Epidemiology Center, 2013).

Microbiological diagnosis

For the confirmation of the disease, it is necessary to take samples from the patient, ideally before the start of antibiotic treatment. Samples will be taken with swabs of Dacron or calcium alginate from the throat, pseudomembranes and nose. In the case of skin diphtheria, samples of the lesions will be sent. The samples will be sent to the reference laboratory for the realization of a culture.

Crops in which there is growth of *C. diphtheriae* will have to be biotyped and the toxigenicity of the strain will have to be confirmed. This will require phenotypic and genotypic testing.

The phenotypic tests are based on the Elek test which confirms the strain's ability to produce diphtheria toxin. The production of this toxin allows to confirm the disease. The phenotypic test is the reference test.

Genotypic tests detect the tox gene by performing a PCR. They are easy to interpret and quick to perform, but a positive result does not confirm the disease since there are strains of *Corynebacterium* that have the tox gene and yet biologically do not express it, so they are not toxigenic strains.

Treatment

As soon as there is a suspected case, start treatment with diphtheria antitoxin, after taking clinical samples, although there is no diagnostic confirmation. The antitoxin does not neutralize the diphtheria toxin once it has penetrated the cell interior and the delay in its administration is related to the lethality of the disease due to remote complications. Administer 20,000–120,000 U (children 2000–5000 U/Kg) preferably via i.v.

Antibiotic treatment has the utility of destroying microorganisms to stop the production of diphtheria toxin. An intravenous or oral macrolide or penicillin procaine 600,000 IU/12 h i.m may be used until symptoms improve. Complete with amoxicillin 500 mg/8 h until 14 days. Therapeutic alternatives in case of allergy can be Cotrimoxazole, clindamycin, rifampicin and linezolid (Mensa et al., 2021).

If there is respiratory distress, it may be necessary to perform a tracheostomy or intubation in order to maintain the supply of oxygen to the body.

The patient will have to be vaccinated after treatment since the disease does not confer in all cases natural immunity (Vaccine Advisory Committee (CAV-AEP), 2018; Diphtheria Vaccine, 2017).

It is important to confirm pharyngeal eradication by performing a culture from 2 weeks after the end of the antibiotic regimen. In the case of persistence of the bacterium, it is necessary to elongate the treatment 14 more days (European Centre for Disease Prevention and Control, 2021).

Patients with pharyngeal diphtheria require drop-type or contact-type isolation precautions in the case of cutaneous diphtheria. Action by public health agencies is needed to limit the spread of the disease through contact tracing.

Early administration of diphtheric antitoxin because it only neutralizes circulating toxin. Adult dose of 20,000–120,000 U. Treatment for children should be adjusted according to weight, 2000–5000 U/kg. It should be administered intravenously or intramuscularly according to severity and days of disease evolution. Antibiotic treatment with penicillin procaine 600,000 IU/12 h or a macrolides i.v. Administer if there is improvement of the patient amoxicillin 500 mg/8 h orally for 10–14 days in total. In case of intolerance to the previous treatment clindamycin, rifampicin, linezolid and cotrimoxazole may be used (Mensa et al., 2021).

It may be necessary to intubate the patient if the breathing is compromised. The patient will have to be vaccinated once the disease has been overcome, along with the request for a culture in the oropharyngeal zone to confirm the eradication of the microorganism.

Corynebacterium striatum

Pathogenesis and clinical manifestations

Multidrug-resistant strains of *Corynebacterium striatum* have frequently been associated with nosocomial outbreaks with high mortality. Some research has described this microorganism as potentially resistant. The main theory is based on the combination of two main factors:

The first factor is the existence of antibiotic resistance emerging from cross-resistance to antiseptics and disinfectants that are widely used in industrialized countries for cleaning hospitals to control nosocomial infections.

The second factor is the presence of these infections more frequently in immunocompromised patients, in patients with chronic respiratory diseases, with prolonged hospital admissions in surgical or intensive care rooms, in patients in whom invasive medical devices have been used and who had been treated with various antibiotic guidelines (Silva-Santana et al., 2021).

To this should be added its ability to modify the wall in order to reduce its permeability, the high lipid content and the ability to form biofilms (Rasmussen et al., 2020) implies favorable conditions for these bacteria to adhere to venous catheters constituting a risky environment and that can also contribute to increase their tolerance to various antimicrobials (Souza et al., 2019, 2020).

Because of the above, *Corynebacterium striatum* can produce foreign material infections (Kalt et al., 2018), catheter infections, bacteremia and endocarditis, surgical wound and soft tissue infection, abscesses, synovitis, arthritis, meningitis, respiratory infections such as empyema pneumonia, peritonitis endometritis, mastitis, urinary tract infection and eye infections such as conjunctivitis and keratitis.

Treatment

Hospital *C. striatum* strains may have resistance genes, such as the erm(X) gene against erythromycin and clindamycin, the tetA and tetB genes against tetracyclines and oxacillin, the cmx and aphA1 genes encoding resistance to aminoglycosides and chloramphenicol and may also acquire resistance to beta-lactams and quinolones (Mensa et al., 2021; Campanile et al., 2009).

Drugs such as vancomycin, teicoplanin, daptomycin (resistance to this antibiotic can appear quickly), linezolid and imipenem maintain good activity (Reddy et al., 2012).

Corynebacterium amycolatum, Corynebacterium jeikeium, Corynebacterium resistens and Corynebacterium urealyticum

Pathogenesis and clinical manifestations

C. amycolatum: it is part of the normal microbiota of the skin and being one of the Corinebacteria found most frequently in human clinical samples. In the clinical laboratory is isolated in blood cultures as a possible producer of bacteremia in immunocompromised patients, sepsis, endocarditis on native valve, infection of prosthetic material (catheters, heart valves, arthroplasties, pacemakers, etc.), osteoarticular infections, meningitis, surgical wound infection, urinary tract infection, prepubertal vaginitis, breast abscess and as a producer of otitis media.

C. jeikeium: It is part of the axillary and perineal microbiota. It causes diseases in patients with long periods of hospitalization who have been prescribed broad-spectrum antibiotics. This microorganism causes infections such as sepsis (Rasmussen et al., 2020), pleuropulmonary infection, rash, intravascular catheter infections, meningitis or endocarditis in prosthetic valves, especially in immunocompromised persons, neutropenic patients or patients with acquired immunodeficiency syndrome. In diabetics it can produce gangrene and malignant otitis externa.

C. resistens: in bacterial cultures it is visualized as grayish-white, bright, pearlescent colonies up to 1.0 mm in diameter after 48 h of incubation in TSA with sheep blood of 5%. It has lipophilic characteristics. If Tween 80 is added to a concentration of 1% the colony increases its growth to 2–3 mm. It mainly produces rapidly deadly bacteremia in immunocompromised patients and abscesses in different anatomic zones (Otsuka et al., 2005).

C. urealyticum: usually is an opportunistic pathogen of the urinary tract. It takes advantage of favorable circumstances, such as previous antibiotic regimen associated with hospital maneuvers such as probing, urological surgery, cystoscopies. It produces acute or chronic cystitis, fouling cystitis, pyelonephritis and sepsis of urinary origin. It can also produce other pathologies typical of an opportunistic pathogen, such as bacteremia, endocarditis, osteomyelitis, skin infections and soft tissues.

Treatment

Because these strains may have resistance genes to several antibiotics, it is essential to perform sensitivity tests in microbiology laboratories. These tests are intended to confirm the possibility of treatment with erythromycin, quinolones, rifampicin, doxycycline and fosfomycin.

It is best to start treatment with antibiotics that are often sensitive such as linezolid, tigecycline, daptomycin and glucopeptides.

In the case of *C. urealyticum* it may be necessary along with antibiotic treatment the elimination of foreign bodies such as urinary tubes. Endoscopy may also be required to remove mucosal fouling from the urinary bladder along with treatment to acidify urine (Mensa et al., 2021).

Corynebacterium glucuronolyticum

Pathogenesis and clinical manifestations

Corynebacterium glucuronolyticum is usually an opportunistic pathogen can produce infections in humans, such as bacteremia, peritonitis and granulomatous mastitis, but is mainly involved in pathologies of the male genitourinary tract by which it has some specificity.

It highlights its important role as an infectious agent of embedded cystitis in men, in addition to generating male non-gonococcal urethritis and also persistent bacterial prostatitis chronic paucisymptomatic monomicrobial, appearing abundantly in semen samples (Mestrovic, 2018).

Its role has become more relevant recently because its presence in clinical samples was not investigated and its detection was not part of the basic diagnostic protocols of genitourinary tract infections (Ruiz-Pino et al., 2019).

Treatment

Corynebacterium glucuronolyticum is usually sensitive to beta-lactam antibiotics, gentamicin, cotrimoxazole and vancomycin. It is often resistant to fluoroquinolones and macrolides.

Corynebacterium macginleyi

Pathogenesis and clinical manifestations

Bacteria with lipophilic characteristics. Fermentative metabolism. In the bacterial culture there are colonies of corynebacteria of convex morphology and small size, typical of lipophilic *Corynebacterium*, with pink appearance (Riegel et al., 1995). It causes eye infections such as keratitis, postsurgical endophthalmitis and conjunctivitis. Less frequent as etiology of bacteremias, respiratory infections associated with mechanical ventilation, aortic abscess, endocarditis and surgical infection.

Treatment

It may show antimicrobial susceptibility to amikacin, gentamicin, chloramphenicol. Increased resistance to fluoroquinolones is described (Muñoz Lorenzo, 2015).

Introduction

The aerobic actinomycetes is a group of Gram-positive filamentous bacillary organisms that grow better under aerobic than anaerobic conditions. The term “actinomycete” derives from the Greek words “actino” as ray and “mycete” as fungus. Because, they are characterized by their peculiar morphology to undergo complex cellular differentiation like filamentous fungi. They tend to form branches, filaments and spores, being in the past, known as fungi as they true hyphae. The aerobic actinomycetes are known to be an evolutionary heterogeneous assemblage of divergent genera belonging to the phylum *Actinobacteria*, in the class *Actinobacteria* (McNeil and Brown, 1994; Conville and Witebsky, 2011). The heterogeneity of this phylum, one of the largest within the Bacteria domain, in terms of morphology, physiology, metabolism and genome, reflects its biodiversity (Ventura et al., 2007; Barka et al., 2015). Most of them are free-living organism, widely distributed in different terrestrial and aquatic ecosystems, natural or man-made (Goodfellow and Williams, 1983), with interest in human and veterinary medicine, ecology and biotechnology. They have an full-scale secondary metabolism, producing about two-thirds of natural derived antimicrobials, as well as anticancer, immunomodulators agents and others bioactive compounds (Mochon et al., 2016; Barka et al., 2015; Nouioui et al., 2018). The taxonomy of aerobic actinomycetes is not an easy matter, with frequent incongruities, pitfalls and emmendations. Fortunately, the data of the new genomic and proteomic technologies can provide a better understanding of this phylum than those previously available with the polyphasic taxonomy (genotypic and phenotypic data) (Nouioui et al., 2018; Tamura et al., 2018). In fact, the backbone of taxonomic studies, the analysis of the 16S ribosomal RNA (rRNA) gene sequence, is too conserved to distinguish two closely related species in many cases (Conville et al., 2017). The common application of whole-genome sequencing (WGS) for comparative genome hybridization (CGH), average nucleotide sequence identity and average amino acid sequence identity (ANI)/ (AAI), differences of guanine-plus-cytosine (G + C) content in bacteria with their respective cut-offs (>70%, >94%, and <1%, respectively) could be of help to delineated taxonomy of this phylum (Achtman and Wagner, 2008; Sangal et al., 2016; Moore et al., 2010).

At the time of writing, the majority of human pathogens of the aerobic actinomycetes group are placed in the order *Mycobacteriales* with the genera *Corynebacterium*, *Gordonia*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, and *Tsukamurella* (Tindall, 2019; Parte et al., 2020). Until recently, they were included in the order *Corynebacteriales* (Goodfellow and Jones, 2012; Nouioui et al., 2018). With the

Fig. 1 Current classification of genera of aerobic actinomycetes considered to be human pathogens according to the List of Prokaryotic Names with Standing in the Nomenclature (<https://lpsn.dsmz.de/>) (date of accession 18 May 2021) (Parte et al., 2020). The name *Corynebacteriales* (Goodfellow and Jones, 2015) is not the earliest validly published name, being replaced by *Mycobacteriales* (Cavalier-Smith, 2002), meanwhile a solution may be in sight (Tindall, 2019).

phylogenomic data, a possible reclassification of this order *Mycobacteriales/Corynebacteriales* is possible (Vázquez-Boland and Meijer, 2019; Salam et al., 2020). They have a high content of G + C in their genomes and mycolic acids (chemotype IV) in their cell walls. The current classification according to the List of Prokaryotic Names with Standing in the Nomenclature (<https://lpsn.dsmz.de/>) (Parte et al., 2020) is shown in Fig. 1.

Among the extensive phylum *Actinobacteria*, only few genera possess clinical significance in human or veterinary or plant health. They are rarely considered a part of the normal human flora, and mainly cause opportunistic infections, except *Mycobacterium tuberculosis* complex, *Mycobacterium leprae*, and *Dermatophilus* (Saubolle, 2009). In the last decades, these infections have raised due to the increase of the immunosenescent population, and of those patients with immunosuppression conditions and underlying diseases (transplant recipients, neoplasia and leukemia, chronic lung disease, AIDS, corticosteroid treatment). With an acquisition from environmental source by inhalation or traumatic inoculation, the spectrum of disease in human is wide, which may differ greatly between the genera and even between species, but which also may have a great amount of overlap. Many times the infections caused by aerobic actinomycetes are infradiagnosed, because the clinical significance of many species is not clear or the methods for identification fail (McNeil and Brown, 1994; Conville and Witebsky, 2011; Barka et al., 2015; Conville et al., 2017).

This chapter deals only genera with most impact on human health care, excluding *Corynebacterium* and *Mycobacterium* (deal in others chapters). Despite the fact, the prevalence of specific genera and species varies geographically, *Nocardia* spp. is the main etiological agent followed by far by *Rhodococcus* spp., *Gordonia* spp. and *Tsukamurella* spp., with the increase of the mycetoma cases by *Streptomyces* spp. and *Actinomadura* spp. A better understanding of their characteristics as habitat, pathogenesis and immunity, diagnosis, identification and typing, clinical and epidemiological features, antimicrobial susceptibility and therapy is recommendable, to achieve a good outcome of the infections produced by aerobic actinomycetes.

Nocardia

Nocardia genus is the most common aerobic actinomycete isolated as human pathogen. Genus type of the family *Nocardaceae*, *Nocardia asteroides* is the type species, although in the past it was also *Nocardia farcinica* (Goodfellow, 2012). From the description of this genus (Nocard, 1888; Eppinger, 1891), its taxonomic classification has always been a challenge due to the misidentification of the type strain, the reassignment of species to diverse genera (*Actinomadura*, *Amycolatopsis*, *Oerskovia*, *Rhodococcus*, and *Rothia*), the presence of complexes in the same or neighboring species, and the description of new species through identification by genetic, genomic and proteomic techniques (Lechevalier, 1976; Goodfellow and Jones, 2012; Nouiouei et al., 2018). At the time of writing, the genus contains 114 species with validly published names (Parte et al., 2020). More than 90 *Nocardia* species have been recovered

in human samples, being several species unusual causes of a wide spectrum of clinical diseases in both humans and animals. The most common species isolated in clinical specimens are *N. asteroides*, *Nocardia brasiliensis*, *Nocardia cyriacigeorgica*, *N. farcinica*, *Nocardia nova*, *Nocardia otitidiscaviarum*, and *Nocardia transvalensis* (Ambrosioni et al., 2010; Tremblay et al., 2011; Chen et al., 2014; Hardak et al., 2012; Valdezate et al., 2017; Lebeaux et al., 2019; Huang et al., 2019; Tan et al., 2020). *Nocardia* spp., is an opportunistic pathogen, that mainly affects lungs and frequently disseminates to other sites including the central nervous system both immunosuppressed and in apparently immunocompetent people (Saubolle and Sussland, 2003; Coussement et al., 2016; Paige and Spelman, 2019; Wilson, 2012).

Members of the genus are aerobic, Gram-stain positive or gram-variable, weakly acid-fast, non-motile, and mycolic acid-containing actinomycetes. They form an extensively branched mycelia and substrate hyphae (0.5–1.2 µm in diameter) that fragment into rod-shaped or coccoid elements. Macroscopically, visible aerial hyphae may be lacking, sparse, or very abundant, which grow on the surface and penetrate agar media (Goodfellow and Jones, 2012; McNeil and Brown, 1994). The genome sizes of *Nocardia* strains can range from 6.00 Mb (*Nocardia paucivorans*) to 10.52 Mb (*Nocardia miyunensis*), with an average of 7.86 Mb. *Nocardia vinacea* showed the lowest DNA G + C content (65.5 mol%), whereas *Nocardia harenae* has the highest (72.0 mol%) (Tamura et al., 2018).

Habitat

This organism possesses a ubiquitous nature, able to localize in different types of ecological niches. In fact, they are among the most predominant actinobacteria of the soil microbiota, including that of the extreme biosphere (Bull and Asenjo, 2013). *Nocardia* spp. species are found everywhere from sludge and soil to contaminated soil water, foaming coastal marine waters, deep-sea sediments, lake, and desert habitats (Goodfellow and Jones, 2012; Mohammadipanah and Wink, 2016). Some species even infect plants and animals (Yaemsiri and Sykes, 2018; Yasuie et al., 2017). Climate, temperature, humidity, pH and type of soil influence the concentration and diversity of *Nocardia* species founded in the different geographical areas (Andalibi et al., 2015). Like other actinomycetes, *Nocardia* spp. contribute to soil health, playing major roles in the cycling of organic matter, inhibiting the growth of plant pathogens, and decomposing complex mixtures of dead plants and animals (Bhatti et al., 2017).

Pathogenesis and immunity

Nocardia species are an optional intracellular organism, able to survive and multiply inside the macrophage and host tissue. This genus neutralize the activity of the macrophage and the oxidative killer mechanism, with the reduction of the phagosome-lysosome fusion and the intracellular acid phosphatase levels in macrophages, with the production superoxide dismutase, catalase, toxins and cell wall glycolipids (Beaman et al., 1985). Other virulence genes were observed in the analysis of the genome as caseinolytic peptidases, cytolysin, hemolysin, lipases, metalloproteases, phosphatases, phospholipase able to destroy tissues along with hydrolases, mammalian cell invasion genes, esterases, hemagglutinin, the antigen 85 complex family, ESX-1, and sortase A among others (Vera-Cabrera et al., 2012; Gonzalez-Carrillo et al., 2016; Yasuie et al., 2017; Carrasco et al., 2017; Nouiouui et al., 2020). The *Nocardia* cell wall deficient variants (L-forms) are involved in pathogenesis in in vivo animal models and contribute to latency of disease (Beaman, 1980). Lung macrophages and T-cell mediated immunity play a key role in the local control of *Nocardia*. So, invasive nocardiosis mostly affect patients receiving any immunosuppressive agent and particularly with systemic corticosteroid therapy that causes a selective suppression of the Th1-cellular immunity (Margalit et al., 2020a; Lafont et al., 2020).

Diagnosis, identification and typing

In the direct Gram smears, *Nocardia* species appear as very long, branching, thin, and finely beaded rod. But, in the smears of cultures they appear as streptococcus-like chains or as small filaments. They are usually partially acid-fast due to the presence of intermediate-length mycolic acids in their cell wall. Although, Gram stain is more sensitive than the modified acid-fast (Kinyoun) stain (Saubolle and Sussland, 2003; Brown-Elliott et al., 2006). *Nocardia* spp. grow on most routine media, but buffered charcoal-yeast extract agar or modified Thayer-Martin medium may enhance their recovery. The colonial morphology will vary according to species, isolate, medium, incubation temperature and with the time of growth. Growth is aerobic, producing chalky, matt or velvety colonies of different colors (brown, tan, pink, orange, red, purple, grey or white) as it is shown in Fig. 2A–H. Soluble brown or yellow pigments may be produced. They are susceptible to the decontamination methods (*N*-acetyl-L-cysteine, etc.) Prolonged incubation from samples of patients with suspicious nocardiosis are recommended (Conville and Witebsky, 2015; UK Standards for Microbiology Investigations, 2016).

Conventional culture identification based on phenotypic methods (casein, tyrosine, xanthine, hypoxanthine together with other substrates) lacks enough sufficient discriminatory power and it has long turnaround time. The drug pattern type is also of help to the presumptive identification (Brown-Elliott et al., 2006). So, both are surpassed by the great advantage of the molecular techniques, essential to obtain an accurate identification (Tamura et al., 2012). PCR base on the sequencing of housekeeping genes of *rrs* (gene coding for 16S rRNA), *hsp65* (heat-shock protein 65), *secA* (preprotein translocase ATPase), *rpoB* (β-subunit of RNA polymerase), *gyrB* (β-subunit of DNA gyrase), *sodA* (superoxide dismutase) genes, and 16-23rRNA intergenic spacer region (Chun and Goodfellow, 1995; Clinical and Laboratory Standards Institute, 2008; Rodríguez-Nava et al., 2006; Kong et al., 2010; Takeda et al., 2010; Sánchez-Herrera et al., 2017). The 16S rRNA gene sequencing is the gold standard for *Nocardia* identification. But, due to the

Fig. 2 Morphology of colonies of clinical strains of several aerobic actinomycetes grown on Columbia agar (with 5% of sheep blood) with 3–5 days of incubation: (A) *Nocardia abscessus*; (B) *Nocardia asteroides*; (C) *Nocardia brasiliensis*; (D) *Nocardia cyriacigeorgica*; (E) *Nocardia farcinica*; (F) *Nocardia nova*; (G) *Nocardia otitidiscaviarum*; (H) *Nocardia transvalensis*; (I) *Rhodococcus equi*; (J) *Streptomyces albus*; (K) *Streptomyces cacaoni*; (L) *Actinomadura madurae*; (M) *Gordonia bronchialis*; (N) *Gordonia polyisoprenivorans*; (O) *Gordonia sputi*; (P) *Gordonia terrae*; (Q) *Tsukamurella tyrosinosolvens*; (R) *Tsukamurella pulmonis*. Photos have been taken by N. Garrido (National Centre of Microbiology. Reference and Research Laboratory for Taxonomy).

insufficient interspecies polymorphisms to differentiate some species, multiple copies to cause species misidentification, polymorphisms for a single species, and inability to distinguish species belonged to the same complex, make it necessary to complement the identification with another the mentioned above molecular targets or to combine them in a MLSA (multilocus sequence analyzes). The PCR-RFLP (restriction fragment length polymorphism) 16S rRNA and *hsp65* genes was also applied for identification, but the presence of different patterns and/or extrabands limits its use (Fatahi-Bafghi, 2018).

Nocardia species can be rightly identified by the matrix-assisted laser desorption ionization-time of flight mass spectrometry [(MALDI-TOF MS)] when a wide and varied *Nocardia* library is used. However, there are limitations of commercial databases for providing accurate identifications. While some species are only identified at complex level (*N. abscessus* complex, *N. brevicatena*, *N. paucivorans* complex, *N. nova* complex, and *N. transvalensis* complex), others species showed variation in the spectral profiles (as *N. cyriacigeorgica*) and uncommon species are not enough included in the library (Blosser et al., 2016; Carrasco et al., 2016; Conville et al., 2017). In addition, incubation time, culture media and extraction method influence the specie assignation (Verroken et al., 2010; McTaggart et al., 2018). For typing purposes, *gyrB* gene, MLSA, together with pulsed-field gel electrophoresis and random amplified polymorphic DNA-polymerase PCR and amplified fragment length polymorphisms were used (Kalpoe et al., 2007; McTaggart et al., 2010; Carrasco et al., 2013; Gnanam et al., 2020).

The most current taxonomy for *Nocardia* species (Conville et al., 2017) showed the presence of the following complexes: the *Nocardia abscessus* complex includes *N. abscessus*, *Nocardia arthritis*, *Nocardia asiatica*, *Nocardia beijingensis*, and *Nocardia pneumoniae*; the *Nocardia nova* complex includes *Nocardia africana*, *Nocardia aobensis*, *Nocardia cerradoensis*, *Nocardia elegans*, *Nocardia kruczakiae*, *Nocardia mikamii*, *N. nova*, *Nocardia vermiculata*, and *Nocardia veterana*; the *N. farcinica* complex includes *N. farcinica* and *Nocardia kroppenstedtii*; the *Nocardia transvalensis* complex includes *Nocardia blacklockiae*, *N. transvalensis*, and *Nocardia wallacei*. Their relationships among them and respect to other *Nocardia* species could be observed in the phylogenomic tree of Fig. 3.

Fig. 3 *Nocardia* species phylogenomic tree inferred with FastME from GBDP distances determined with NCBI's assemblies. The results were provided by the Type Strain Genome Server (TYGS) (<https://tygs.dsmz.de>, accessed on 2nd April 2021) (Meier-Kolthoff and Göker, 2019). The adscription to different nodes is indicated by the different colors of species' names.

Clinical and epidemiological features of *Nocardia* infections

This environmental organism is mainly acquired by inhalation and traumatic inoculation, being pulmonary nocardiosis and mycetoma the most common entities. More than 60% of the nocardiosis cases present pulmonary involvement (Ambrosioni et al., 2010; Tremblay et al., 2011; Hardak et al., 2012; Valdezate et al., 2017; Fatahi-Bafghi, 2018; Huang et al., 2019). Cough and fever were the most common symptoms, but dyspnea, sputum and weight loss also appear. The inflammatory parameters (C-reactive protein and white blood cell count) were moderately elevated. One or more nodules or masses and pulmonary airspace consolidations were the most frequent radiologic abnormalities, and cavitation mostly occurred within 2 weeks (Chen et al., 2014). Some of these manifestations can be seen in Figs. 4–6 Chen et al. (2014). Right upper lobe is mainly involved (53.9%), perhaps because is one of the best ventilated areas (Ott et al., 2019). Owing to the non-specific clinical appearance of pulmonary nocardiosis, which mimic with pulmonary tuberculosis, invasive fungal disease and lung cancer, the median time to final diagnosis was 14–25 days (range 0–54 days) (Chen et al., 2014; Ott et al., 2019). In Germany, the overall average annual age-adjusted hospitalization rate was estimated in 0.04/100.000 inhabitants. With highest rate among men aged 75–84 years (0.24/100000) (Ott et al., 2019). Although, pulmonary nocardiosis associated with an underlying autoimmune disease showed a female predominance and presentation at younger age (Li et al., 2015). The mortality rate has been estimated about 18%, being death most frequent among patients who received immunosuppressive drugs (Chen et al., 2014). In those immunocompromised patients who present new nodules or masses evolving into cavitation in a short amount of time, and suffered from pneumonia with poor response to treatment, a high clinical index of suspicion of pulmonary nocardiosis is necessary for an early diagnosis and timely treatment (Chen et al., 2014).

An important trait of this organism is its ability to disseminate, when infection was present in two non-contiguous organs or in the central nervous system (CNS), and more prevalent in immunocompromised patients. *N. asteroides*, *N. abscessus*, *N. farcinica*, and *N. nova* cause the majority of invasive infections (Saubolle and Sussland, 2003; Lafont et al., 2020). Extrapulmonary sites of infection include the skin and soft tissue, CNS, and bloodstream. Being the CNS the most frequently affected site (Wilson, 2012), due to the special tropism of *Nocardia* for neural tissue from pulmonary or cutaneous infection. Responsible of 2% of all cerebral abscesses, high mortality rates are described in immunocompromised and in immunocompetent patients (55%, and 20%, respectively). Rates that increase to 66% with multiple abscesses (Patel et al., 2019). *Nocardia* brain abscess presents as a slowly progressive mass lesion, with variable signs and symptoms: focal neurologic abnormalities (hemiparesis, and cranial nerve palsies, among others), headache, fever, altered mental status, seizures, visual changes, nausea and vomiting, ataxia and falls (Anagnostou et al., 2014). As consequence that, more than 43% of the CNS nocardiosis case are asymptomatic (Coussement et al., 2016). Routine contrast-enhanced brain imaging is recommended in patients with nocardiosis. Magnetic resonance imaging is preferred

Fig. 4 A 45-year-old man on immunosuppressive therapy after renal transplantation was infected with *Nocardia asteroides*. (A–C) Axial CT images reveal multiple patterns of disease and lymphadenopathy; (D) An axial CT image reveals small pulmonary nodules with relapsed infection two years after the initial diagnosis (Chen et al., 2014). (2014) Clinical and radiographic characteristics of pulmonary nocardiosis: Clues to earlier diagnosis. *PLoS One* 9(3): e90724. <https://doi.org/10.1371/journal.pone.0090724.g002>.

over computerized tomography, appearing as ring-enhancing lesions (Margalit et al., 2021). According to the literature, surgical excision or aspiration of the brain abscess seems to provide good chances of eradication of the disease if the patient demonstrates clinical deterioration or no improvement with the appropriate antibiotic therapy (seen within 1 week) (Patel et al., 2019). *N. farcinica* has been described as a more virulent pathogen with a tendency for disseminated infection, being the main causative agent in CNS nocardiosis (Brown-Elliott et al., 2015; Valdezate et al., 2017; Lebeaux et al., 2019).

Skin and soft tissue infections (SSTIs) could be primary cutaneous nocardiosis due to trauma or other inoculation, including iatrogenic, or secondary cutaneous nocardiosis due to disseminated infection. They include lymphocutaneous, mycetoma, and superficial skin infection, that can be misdiagnosed with fungal, viral or other bacterial infections. Lymphocutaneous infection typically presents as an ulcerated draining lesion at the site of injury accompanied by proximal lymphangitic spread with overlying subcutaneous nodules and often regional lymphadenopathy. Mycetoma is a chronic, slowly progressive infection that often starts as a small nodule at the site of traumatic entry of the pathogen, usually the foot. If left untreated, it can lead to mass-like lesions with destructive granulomata and fistula formation, affecting the underlying tissue and bone with significant disability. Superficial SSTIs can have a quite variable appearance including ulcers, papules, pustules, plaques, nodules, diffuse erythema, and cellulitis as well as abscess and fistula formation. Although many *Nocardia* species produces SSTIs, *N. brasiliensis* is most often associated with skin and soft tissue infections and seen more commonly in tropical and subtropical climates (Brown-Elliott et al., 2006; Hemmersbach-Miller et al., 2019).

Bacteremia, is a rare but serious entity, with high associated overall mortality (40%). It is acquired by disseminated (pulmonary, CNS or SST infections) mainly in immunocompromised patients or by intravascular device-related infection. Frequently, concurrent infections with other pathogens occur (Al Akhrass et al., 2011; Williams et al., 2020). Other nocardiosis infections involve eyes, joints, bones, kidneys (Soleimani et al., 2020; Gnanam et al., 2020). *Nocardia* also affect to cattle, pets, wild animals and fishes, with big economic losses (Eroksuz et al., 2017; Yasuike et al., 2017).

Nocardiosis is rare in humans, with an incidence ranging from 0.33 to 0.87 for 100,000 inhabitants, with high values in some countries (Lafont et al., 2020). It reaches high values in patients with higher degree of immunosuppression. The organ transplant recipients is the most affected population, especially those with lung and heart transplants (Coussement et al., 2016; Paige and Spelman, 2019). But also, nocardiosis can affect until 45% of apparently immunocompetent patients with impaired immunity

(Peleg et al., 2007; Tremblay et al., 2011; Coussement et al., 2017; Majeed et al., 2018; Steinbrink et al., 2018). The population susceptible to infection is increasing due to the increased prevalence of immunosenescent population or/and immunosuppression conditions (Fatahi-Bafghi, 2018; Li et al., 2015) by the presence of some comorbidities as chronic lung disease, neoplasia and leukemia, organ transplant recipients, hematopoietic stem cell transplantation, autoimmune diseases, chronic alcoholism, diabetes mellitus, and AIDS (Ambrosioni et al., 2010; Tremblay et al., 2011; Wang et al., 2014; Li et al., 2015; McGuinness et al., 2016; Margalit et al., 2021).

Immunosuppressive therapy has been associated with nocardiosis (prednisone, calcineurin inhibitor, mycophenolate, cytostatic agent, mTOR inhibitor, and TNF-binding protein), and especially the corticosteroid therapy. Being the systemic corticosteroids strongly associated with pulmonary nocardiosis. In fact, when systemic corticosteroids are adjusted in a study with multivariable model, the positive association between solid organ transplantation and nocardiosis was attenuated. Among individuals diagnosed with nocardiosis, corticosteroid therapy is prevalent, especially in patients with chronic pulmonary disease and pulmonary nocardiosis (Margalit et al., 2020a). Other described risk factor for *Nocardia* acquisition is the traumatic inoculation in the outdoor activities, which may cause skin nocardiosis. Clinical setting in patients with catheterization or surgery could also ease the acquisition (Al Akhrass et al., 2011).

Not always the isolation of *Nocardia* means an evident clinical infection which required therapy. *Nocardia* colonization of the upper respiratory airways can exist in healthy individuals, and in the lower respiratory airways of cystic fibrosis patients or non-CF bronchiectasis, lung transplant recipients or in immunocompromised patients (Vetor et al., 2016; Dagan et al., 2015). A recent study has showed that a significative proportion (20%) of colonization occurs in patients with chronic pulmonary diseases and less frequently in patients with corticosteroid treatment (Margalit et al., 2020b).

Overall *Nocardia* species distribution depends of the geographic location, host and sites of infection, because some species may have a predilection to certain sites (Saubolle and Sussland, 2003; Brown-Elliott et al., 2006; Hemmersbach-Miller et al., 2019). The major pathogenic *Nocardia* species vary depend on the country: *N. nova* predominates in some countries as United States, Canada, and Australia (Uhde et al., 2010; Schlager et al., 2014; Hamdi et al., 2020; Tremblay et al., 2011; Tan et al., 2020); *N. cyriacigeorgica* in Spain (Valdezate et al., 2017); *N. farcinica* in France (Lebeaux et al., 2019); and *N. brasiliensis* in Japan and Taiwan (Kageyama et al., 2004; Wang et al., 2015).

Antimicrobial susceptibility and therapy

A key element for the antimicrobial stewardship is the right *Nocardia* specie assignation. For the most clinically significant *Nocardia* species/taxa, correlation among a determinate drug pattern type is traditionally described as it can be observed in Table 1 (Wallace Jr. et al., 1988; Brown-Elliott et al., 2015). However, the susceptibilities varied for a single species. As consequence, antimicrobial susceptibility testing of the isolates always has been done for an efficient and effective therapeutic management. According to Clinical and Laboratory Standards Institute guidelines (CLSI) (Clinical and Laboratory Standards Institute, 2018a,b), broth microdilution is the recommend method (Uhde et al., 2010; Brown-Elliott et al., 2012; Schlager et al., 2014; Hamdi et al., 2020) with standardized susceptible and resistance breakpoints for *Nocardia* spp. and other aerobic actinomycetes (Clinical and Laboratory Standards Institute, 2018a) as it is seen in Fig. 7. Other alternatives are the E-test or the disk diffusion (Valdezate et al., 2017; Lebeaux et al., 2019). The inoculum preparation due to the bacterial clumps and the time (low/slow) and type growth can difficult the minimum inhibitory concentrations (MICs) reading.

In overall, amikacin, linezolid, and trimethoprim-sulfamethoxazole showed high in vitro activity against most *Nocardia* species. The keystone of nocardiosis treatment is the trimethoprim-sulfamethoxazole, applied empirically before susceptibility results, alone or in combination after testing with other agents (third-generation cephalosporin, imipenem, or amikacin). Linezolid and tedizolid, very active in vitro against almost all *Nocardia* species, enlarged the therapeutic options (Margalit et al., 2021; Soueges et al., 2021).

Resistance against trimethoprim-sulfamethoxazole have been detected in some strains, in special in those belonged to the *N. transvalensis* complex. Regarding other antimicrobials, higher resistance rates are observed for some of main species against: amoxicillin-clavulanic acid in *N. cyriacigeorgica* and in *N. nova* complex; ceftriaxone in *N. brasiliensis*, *N. farcinica*, *N. nova*, and in *N. transvalensis* complex; against imipenem in *N. abscessus* complex, *N. brasiliensis*, and *N. transvalensis* complex. Clarithromycin, minocycline, and ciprofloxacin have showed higher resistance rates except for *N. nova* complex, *N. abscessus* complex, and *N. transvalensis* complex, respectively (Uhde et al., 2010; Brown-Elliott et al., 2012; Schlager et al., 2014; Valdezate et al., 2017; Lebeaux et al., 2019; Hamdi et al., 2020).

Two tentative definitions of multidrug-resistant (MDR) for *Nocardia* have been proposed: (i) an isolate is defined as MDR if it is non-susceptible (resistant or intermediate) to 2 or more of the most commonly used empirical agents (amikacin, ceftriaxone, imipenem, and TMP-SMX) (Schlager et al., 2014); (ii) MDR (non-susceptibility to ≥ 1 agent in ≥ 3 antimicrobial categories of CLSI), XDR (non-susceptibility to ≥ 1 agent in all but ≤ 2 categories), and pandrug resistance (PDR; non-susceptibility to all antibiotics) (Valdezate et al., 2017), excluding intrinsic non-susceptibility to a specific antimicrobial for a given specie (Magiorakos et al., 2012). Higher MDR rates were detected in *N. brasiliensis*, *N. farcinica*, and *N. transvalensis* complex (Valdezate et al., 2017; Hamdi et al., 2020) highlighting the importance of survey in the main species.

At this moment, no consensus exists on the optimal management of nocardiosis, but some proposals have been done, as it can see in Table 2 (Margalit et al., 2021). A combination of targeted antimicrobial treatment based on the antimicrobial susceptibility profile of the infecting nocardial strain, which include trimethoprim/sulfomethoxazole for more than 6 months, and neurosurgical intervention is recommended for CNS nocardiosis (Anagnostou et al., 2014). Always, therapy must be tailored to the individual

Table 1 Major antimicrobial susceptibility patterns of clinically significant *Nocardia* species and complexes.

Species and complexes ^a	Drug pattern type	Susceptibility ^b

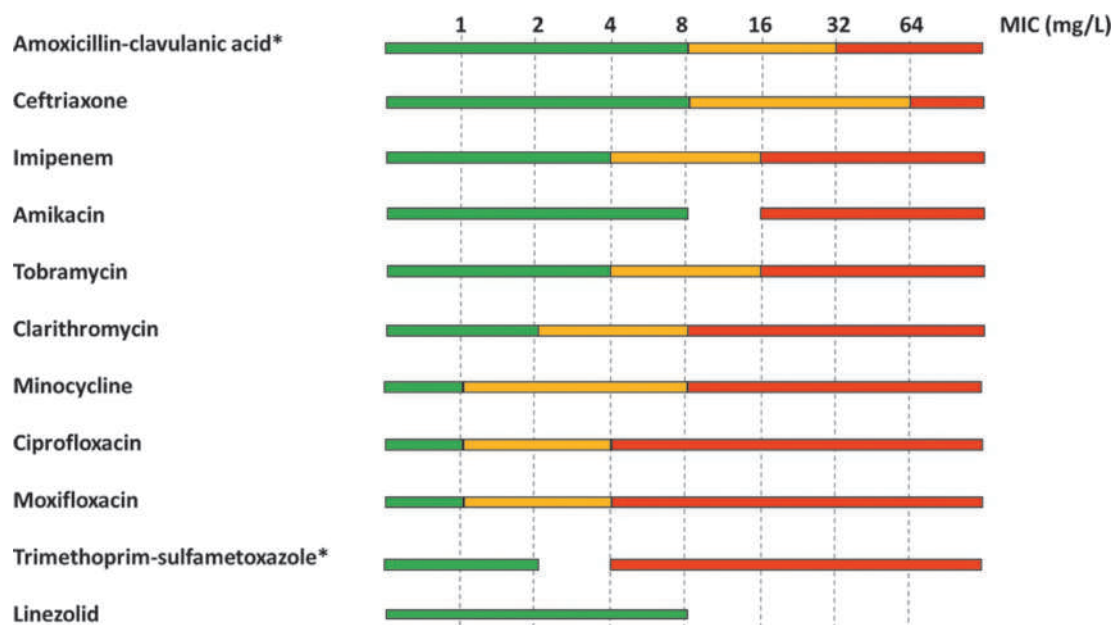

Fig. 7 Antimicrobial categories traffic light. Tentative breakpoints proposed for *Nocardia* species and other aerobic actinomycetes (except *Rhodococcus equi*). Categories are indicated as susceptible with a green bar, intermediate with an orange bar, and resistant with a red bar. *Combinations for amoxicillin-clavulanic acid (8/4, 16/8 and 32/16 mg/L) and trimethoprim-sulfamethoxazole (2/38 and 4/76 mg/L) were considered. Source: CLSI standard M24-A2, Clinical and Laboratory Standards Institute (2018b) *Performance Standards for Susceptibility Testing of Mycobacteria, Nocardia spp., and Other Aerobic Actinomycetes*. CLSI Supplement M62. Clinical and Laboratory Standards Institute: Wayne, PA.

patient based on species-specific susceptibility patterns and formal susceptibility testing, site(s) of infection, and patient tolerability (Hemmersbach-Miller et al., 2019). The prognosis for nocardiosis is variable, depending on the affected organ, the immune status of the patient, and the characteristics of the implicated specie.

Bioactive secondary metabolite production

When the metabolic potential of *Nocardia* is assessed, a plethora of putative biosynthetic gene clusters of various classes, including polyketide, nonribosomal peptide, and terpenoid pathways have revealed. *Nocardia* represent a prolific source for natural products rivaling better-characterized genera such as *Streptomyces* (Barka et al., 2015; Männle et al., 2020).

Table 2 A proposed algorithm for the management of a patient with nocardiosis.

<i>Nocardiosis extent</i>	<i>Primary skin</i>	<i>Isolated pulmonary</i>	<i>Dissemination^a without CNS involvement</i>	<i>CNS involvement</i>
Initial treatment (i.e., before species identification and AST results)	SxT ^b Possible alternative: LZD ^b	SxT ^b ± IMI or AMK or CRO or CTX ^b Possible alternatives: LZD ± IMI or CRO or CTX ^b Monotherapy (e.g., with SxT) is probably appropriate in selected patients with non-severe pulmonary nocardiosis	SxT ^b ± IMI or AMK or CRO or CTX ^b Possible alternatives: LZD ± IMI or CRO or CTX ^b	SxT with IMI ± AMK ^{b,c} Possible alternative: LZD with IMI ^b
Microbiology	Systematic species identification and antimicrobial susceptibility testing (if <i>Nocardia</i> identified to the species level but AST still pending)			
Brain imaging	Systematic brain imaging (MRI or contrast-enhanced CT) for all individuals with nocardiosis (only possible exception: immunocompetent patients with primary skin nocardiosis)			
Chest imaging	Systematic chest CT for all individuals (only possible exception: immunocompetent patients with primary skin nocardiosis)			
Maintenance therapy	If initial treatment was a multi-drug regimen with intravenous agents: continue for 2–6 weeks Therapeutic modifications based on response to therapy, microbiology results, and patient specificities			
Switch to oral therapy (if indicated, when the clinical response is favorable)	SxT ^b (possible alternatives, including MIN or AMC ^b)			SxT ^b
Total duration of antimicrobial therapy	3–6 months (shorter durations may be appropriate for immunocompetent patients)	6 months (3–4 months may be appropriate for selected patients with good response to therapy and treatment complicated by side-effects)	6–12 months (depending on the response to therapy and individual specificities)	9–12 months (possibly longer)
Secondary prophylaxis	Not indicated in immunocompetent patients (very low risk of relapse) SxT prophylaxis ^b may be considered in immunocompromised patients (if well tolerated)			
Intravascular device removal	Not indicated			Required in device-associated bacteremia and endocarditis

CNS, central nervous system; SxT, trimethoprim-sulfamethoxazole; AMC, amoxicillin-clavulanic acid; CTX, cefotaxime; CRO, ceftriaxone; IMI, imipenem; AMK, amikacin; MIN, minocycline; LZD, linezolid; MRI, magnetic resonance imaging; CT, computerized tomography; IV, intravenous.

^aDissemination is defined as the involvement of ≥ 2 non-contiguous organs.

^bTreatment regimens: trimethoprim-sulfamethoxazole: 10–20 mg trimethoprim/kg/day (possibly lower dose in patients with primary skin nocardiosis), secondary prophylaxis: daily oral at least 800/160 mg (unclear effectiveness, and breakthrough nocardiosis described while on 800/160 mg once daily); linezolid: IV, oral: 600 mg twice daily; minocycline: oral: 100–300 mg twice daily; amikacin: IV: 20–30 mg/kg/day; ceftriaxone: IV: 2000 mg once daily or twice daily if CNS involvement; cefotaxime: IV: 2000 mg three times daily or 4000 mg three times daily if CNS involvement; imipenem: IV: 500 mg four times daily: Dose adjustment for renal function is required for the following drugs: trimethoprim-sulfamethoxazole, amikacin, cefotaxime, and imipenem.

^cThe addition of amikacin may be discussed despite limited CNS penetration.

Modified from Margalit I, Lebeaux D, Tishler O et al. (2021) How do I manage nocardiosis? *Clinical Microbiology and Infection* **27**: 550–558. <https://doi.org/10.1016/j.cmi.2020.12.019>.

Rhodococcus

Previously classified as *Corynebacterium*, *Prescottia*, and *Prescottella*, this genus belonged to the family *Nocardiaceae*, being the type specie *Rhodococcus rhodochrous*. At the present time, *Rhodococcus* genus (Zopf, 1891) includes 51 species with validly published and correct names (Parte et al., 2020) and about 800 genome assemblies of 37 species are available. Two species are recognized as pathogenic *Rhodococcus fascians*, which causes leafy gall in plants (Stes et al., 2013), and *Rhodococcus equi* (Vázquez-Boland and Meijer, 2019). The genus *Rhodococcus* is obligate aerobic, Gram-positive, partially acid-fast, catalase-positive, non-motile, and none-endospore bacteria. Without flagellum, sometimes a few numbers of pili may exist in this genus. They showed a pleomorphic shape with coccobacillus appearance in solid media and tissue, and filamentous and branched form in liquid media. Members of this genus producing red pigment. Most strains of this genus grow well in conventional medium, but some species require thiamin (vitamin B1) for their growth (McNeil and Brown, 1994).

Rhodococcus equi is a zoonotic organism that can cause rare, potentially fatal, pulmonary and extrapulmonary pyogranulomatous disease in animals and people. It is well-known as a major horse pathogen, and it predominantly affects immunocompromised people (Verville et al., 1994; Yamshchikov et al., 2010; Majidzadeh and Fatahi-Bafghi, 2018). Its circular chromosome has a G + C content of 68.8% with a size of 5.04 Mbp, more compact than environmental rhodococci. It appears genetically stable, with absence of significant recombination and unfrequent insertion sequences, but with a significant contribution of horizontal gene transfer (Anastasi et al., 2016). A special feature of *R. equi*, also shared with *M. tuberculosis* within Actinobacteria is the absence of phosphoenolpyruvate:carbohydrate transpot system (PTS), it might be associated with adaptation to intracellular niche. Other special feature, but in the *Rhodococcus* genus, is the presence of large circular or linear conjugative plasmids which carry genes encoded virulence determinants and detoxification pathways to survive in xenobiotic-contamination ecosystems (Vázquez-Boland and Meijer, 2019).

Habitat

Rhodococcus species is a soil-borne organism that is widespread in the environment, particularly in soil but also in aquatic reservoirs as rivers, lakes. This organisms is eliminated through the feces of animals. Exposure to soil contaminate with herbivore manure is likely the major route of both animal and human infection. This pathogen has been isolated from feces of a wide variety of animal species, including equines, bovines, small ruminants, dogs, pigs, and some wildlife (McNeil and Brown, 1994; Majidzadeh and Fatahi-Bafghi, 2018). Recently, the main responsible to cause infections, *R. equi* has been isolated from the feces of cats which had a history of contact with horses and their environment (Lechinski de Paula et al., 2019).

Pathogenesis and immunity

R. equi is an intracellular pathogen, which enter in the phagosomes of the macrophages. It is thought that immunity to *R. equi* relies on cell-mediated immunity via T helper type 1 lymphocytes, with a minor role of the humoral immunity. The inhibition of lysosome-phagosome fusion by this bacteria generates a macrophage killing resistance producing in tissue destruction and neutrophil influx, which ultimately leading to necrotizing pneumonia. The lack of macrophage killing in *R. equi* pneumonia can provokes a granulomatous disease with basophilic intracellular accumulations of iron and calcium inside macrophages named Michaelis Gutman bodies (Giguere et al., 2011).

The intra-macrophage proliferation of *R. equi* is facilitated by virulence associated proteins (VAP), encoded by *vap* genes located on circular and linear plasmids. Three *R. equi* *vap* plasmids have been identified: *vapA*, *vapB*, and *vapN*. According to mouse pathogenicity, the *vapA*-positive strains are classified as virulent and they carry large and circular plasmids (80–90 kb). While *vapB*-positive strains are considered as intermediately virulent and less pathogenic in horse, and carrying plasmids of 20 kb. Virulent strains and intermediately virulent strains are associated with severe pulmonary and systemic infections in foals and *vapB* in lymph node of swine. The last described, *vapN* is initially associated with strains collected from lymph nodes of ruminants. The presence of a specific *vap* plasmids is related with animal host adaptation (MacArthur et al., 2017), being an active exchange across *R. equi* population (Anastasi et al., 2016). In strains with human origin, *vapN* and *vapB* plasmids were more prevalent than *vapA* (43%, 30% and 16%, respectively) (Bryan et al., 2018) or absents (Takai et al., 2020). In addition, the transfer of this plasmids is done by the relaxe TraA.

Diagnosis, identification and typing

A common feature of human *R. equi* infection is the delay in diagnosis. The insidious course of disease contributes to delay, as does failure to identify the organism (Verville et al., 1994). This organism replicates slowly and may not even produce visible colonies unless culture plates are incubated for 48–72 h, contributing further to under-recognition (Fig. 21). Furthermore, *R. equi* on a culture plate may suggest as normal respiratory flora. So, it has recommended to pay attention to microscopic examination of gram-stained specimens (with large numbers of white blood cells with pleomorphic gram-positive coccobacilli) and the replace of sputum sample by aspirated or biopsies samples. In pulmonary infection, *R. equi* positive blood cultures would provide a definitive diagnosis. Although, bacteremia is seen more often in immunocompromised than immunocompetent patients (80%, and 30%, respectively). Too, the presence of necrotic tissue with dense histiocytic infiltrates and eosinophilic granular cytoplasm has been useful to identify *R. equi* pulmonary infection (Scott et al., 1992; Lin et al., 2019).

Take in mind, the importance of the diagnosis of rhodococci, several selective media have been used for isolation of *R. equi* as TINSDALE (selective medium for *Corynebacterium diphtheria*), NANAT medium (Nalidixic acid-Novobiocin-Actidione-Potassium tellurite), CAZ-NB (with Mueller-Hinton agar base, novobiocin, ceftazidime, and cycloheximide) among others (Majidzadeh and Fatahi-Bafghi, 2018). In the last two decades, molecular identification techniques have displaced phenotypic tests [Christie-Atkins-Munch-Petersen test (CAMP), serology, etc.] to distinguishing *Rhodococcus* spp. as 16S rRNA gene sequencing. But, sometimes it is unable to differentiate between closely related species. To specific species detection has been use the *choE* gene (cholesterol oxidase) sequencing and PCR-restriction fragment length polymorphism (RFLP) of the 65 kbp-heat shock protein (*hsp65*) gene. The sequencing of other genes (*catA*, *gyrB*, *alkB*) and of those genes included in the multilocus sequence typing (MLST) scheme (<https://pubmlst.org/organisms/rhodococcus-spp>) [glyceraldehyde-3-phosphate dehydrogenase (*gapdh*), RNA polymerase β /*rpoB*], malate dehydrogenase (*mdh*), adenosine kinase (*adk*), triosephosphate isomerase (*tpi*), isocitrate lyase (*icl*), and recombination and repair systems (*recA*)] allowed more accurate *Rhodococcus* species identification and *R. equi* typing (Duquesne et al., 2017; Dhaouadi et al., 2020). For virulent strains of *R. equi* detection or typing, the detection of the presence of the *traA* gene and *vap* plasmids is of usefulness (Morego et al., 2009; Bryan et al., 2018; Takai et al., 2020).

In a whole-genome phylogeny, the genus *Rhodococcus* appears as a distinct, well-defined monophyletic grouping of the *Mycobacteriales* order. All *R. equi* isolates group in the well-supported monophyletic cluster no. 3 or “equi” subclade, which also contains *Rhodococcus defluvi* Ca11Ts as the closest relative, and *Rhodococcus triatoma*. Other subclades, in general congruent with 16S rDNA clustering are: subclade 1 or “rhodochrous” with two sublineages encompassing *Rhodococcus ruber*, *Rhodococcus rhodochrous* and *Rhodococcus pyridinivorans*; subclade 2 or “erythropolis,” with two sublineages, one containing *Rhodococcus opacus*, *Rhodococcus jostii*, *Rhodococcus imtechensis* and *Rhodococcus watislaviensis*, and the other, *Rhodococcus erythropolis* and *Rhodococcus qingshengii*; a subclades 4 and 5 that correspond to *Rhodococcus rhodnii* LMG 5362 and *R. fascians* isolates (Anastasi et al., 2016).

Clinical and epidemiologic features of *Rhodococcus equi* infections

The vast majority of rhodococcal human infections are caused by *R. equi*. The infections due to *R. defluvi*, *R. erythropolis*, *R. fascians*, *Rhodococcus gordoniae*, and *Rhodococcus ruber* have also been reported as cause of pneumonia, encephalitis, bacteremia and eye infections (Canetti et al., 2019; Baba et al., 2009; Bagdure et al., 2012). *R. equi* infection is characterized by diverse pyogranulomatous clinical disorders in humans, domestic animals, and wildlife. Human diseases consist of endophthalmitis, wound infection, pulmonary infection, osteomyelitis, peritonitis, chronic corneal ulcer, sarcoidosis, brain abscesses, skin and lymphadenitis, actinomycetoma, pulmonary malacoplakia, and purulent meningitis. *R. equi* has also been reported as a case with diffuse large B cell lymphoma (Verville et al., 1994; Majidzadeh and Fatahi-Bafghi, 2018; Lin et al., 2019; Takai et al., 2020).

The most common lesions associated with *R. equi* infection in susceptible patients are cavitating pulmonary abscesses, bacteremia, and lymphadenitis. The involvement of pulmonary sites (lungs, pleura or thoracic cavity) and extrapulmonary sites (brain abscess, skin/soft-tissue, intrathoracic lesion) were reported in nearly 90% and 20%, respectively of AIDS patients (Topino et al., 2010). Meanwhile, in immunocompetent patients are more frequent the extrapulmonary infections (Drancourt et al., 1992; Giguere et al., 2011; Lin et al., 2019). In this way, around 95% of the immunocompromised patients develop an infection with pulmonary involvement, meanwhile do it less than 50% of the immunocompetent patients. For both type of patients, the presence of cavitary lesions located in the upper lobe of lung appears as differential feature of *R. equi* infection by radiologic imaging (Gundelley et al., 2016).

The *R. equi* human infection mainly occur in patients with an immunocompromised status, with organ transplants, with hematological malignancies, with immunosuppressive drugs (corticosteroids, tumor necrosis factor- α inhibitors, prednisone), and with HIV infection. Being HIV infection, with CD4 count <200 cell/mm³ (Capdevila et al., 1997), the main risk factor in *R. equi* pneumonia (61.5%) (Scott et al., 1995). Due to the marked feature of opportunistic infection by *R. equi*, it is important to search in immunocompetent subjects with pneumonia a possible status of immunodepression and in the case of no pulmonary infections, the presence of localized infections such as cutaneous wounds or osteomyelitis (Gundelley et al., 2016).

Similar to humans, zoonotic diseases produced by *R. equi* have been reported as: pneumonia in foals (the major cause), calfs, pigs, sheeps, koalas and marmosets; pyaemia (a type of sepsis that leads to widespread abscesses of a metastatic nature) in foals; pyometra (uterine infection) and mastitis in cows and she-buffalos; abortion in lambs; lymphadenitis in cats, cattles, and seals; abscesses, skin infection and cellulitis in dogs and cats; and liver and spleen lesion in foals in goats. As plant pathogens, *R. fascians* and *Rhodococcus* spp. have been reported in in sweet peas, leafy gallin various plants, cauliflower, strawberry and pistachio plants (Majidzadeh and Fatahi-Bafghi, 2018).

Antimicrobial susceptibility and therapy

Different antimicrobial susceptibility testing methods has been used as broth dilution, E-test, disk diffusion, with $>85\%$ of agreement between them (Riesenberg et al., 2013; Berghaus et al., 2015). Although the first one is the recommended method by CLSI, there is not an available interpretative criteria for the specific categorization of *R. equi* (susceptible-intermediate-resistant) strains. Susceptibility up to 90% for vancomycin, macrolides, carbapenems, ciprofloxacin, and rifampin, with lower values for doxycycline and minocycline haven reported. With resistance rates $>40\%$ for trimethoprim-sulfamethoxazole, ampicillin-sulbactam and clindamycin (Topino et al., 2010). The emergence of resistance to macrolides and rifampin have been cause by erythromycin-resistant methylase gene *erm*(46) and mutations in the resistance-determining region of the RNA-polymerase β -subunit encoded by of *rpoB* gene, respectively. Difference in the antibacterial resistance has been seen in different geographic regions due to selective pression (Giguère et al., 2017).

The *R. equi* infections treatment it not easy. Because to the ability of *R. equi* to survive and replicate in macrophages, the presence of mass lesions or pulmonary cavities, the tendency to recurrence and the immunocompromised status of patient. Being a prolonged (it could be at least 6 months) and combined treatment (two antimicrobials) needed. In fact, the main factor of the success of therapy and its length is the immunological status and the nature of the lesion (Giguère et al., 2017; Lin et al., 2019). So, treatment with bactericidal antibiotics with an effective antiretroviral therapy is mandatory in HIV/AIDs patients, because high mortality (Drancourt et al., 1992). Failures in treatment had been produced in immunocompetent patients with short course treatment with single antibiotics (Lin et al., 2019). Combination treatment with two or three drugs is the mainstay of therapy, with the inclusion of antibiotics with intracellular activity, such as rifampicin and azithromycin, because intrahistiocytic survival remains a major virulence determinant for *R. equi* pathogenesis. For veterinary use, choice of drugs is the a combination of macrolide (erythromycin, clarithromycin or azithromycin) with rifampicin (Yamshchikov et al., 2010). In addition, resection or surgical drainage for abscess or lesions could be required.

Streptomyces

Streptomyces is the largest genus in the Actinobacteria, and also within the bacteria, that includes more than 950 species and 50 subspecies (Parte et al., 2020). The importance of this genus is consequence that they are a valuable source for bioactive commercially significant products (Barka et al., 2015). They belonged to the order *Streptomycetales*, family *Streptomycetaceae*, being the type genus *Streptomyces* and the type species *Streptomyces albus* (Waksman and Henrici, 1943). *Streptomyces* genus has been

subjected to extensively isolation and screening, with a large number of isolates and poor species definition which has provoked an overspeciation and taxonomic chaos (Anderson and Wellington, 2001; Labeda et al., 2012). More than 4000 genome assemblies of 537 species are available. Unlike other bacteria, this genus have a linear chromosome, G-C rich (about 70%), with a large size (6 Mbp–12 Mbp). This linear chromosome is a district property of this genus, and it is highly unstable suffering large rearrangements (Zhou et al., 2011). In addition, three linear plasmids have been detected in the *Streptomyces rochei* specie (Nindita et al., 2019).

Streptomyces produce an extensive branching substrate and aerial mycelium. Growth occurs at the hyphal apices and is accompanied by branching, thus producing a complex tightly woven matrix of hyphae during the vegetative growth phase. As the colony ages, aerial mycelia (sporophores) are produced which develop into chains of spores (conidia) by the formation of crosswalks in the multinucleate aerial filaments. This is followed by separation of individual cells directly into spores (Wildermuth and Hopwood, 1970; Anderson and Wellington, 2001).

The pathogenic role of this genus is difficult to assign, being considered as a mainly as a contaminant. Prevalent in tropical and subtropical regions, *Streptomyces* rarely causes severe invasive infections, but it is the most common cause of actinomycetoma (Dunne et al., 1998; Siddig et al., 2019).

Habitat

Streptomyces species are widespread environmental bacteria, distributed in terrestrial and aquatic ecosystems (deserts, ice in South Pole, insects, plants, lakes, seas, oceans) with soil, fodder, and compost as their primary habitat. In soil, they represent around 1–20% of the total viable count and are known to prefer the characteristic earthy smell (geosmin). *Streptomyces* are chemoheteroorganotrophs and are distinguished by their tough, leathery colonies and filamentous growth. They play an important ecological role in the turnover of organic material participating in numerous biodegradation and bioremediation processes. They are able of using complex organic materials such as carbon and energy sources in the breakdown of these products in the soil. The number and type of *Streptomyces* strains present in a particular soil are greatly influenced by environmental conditions such as temperature, pH, amount of organic matter, aeration etc. (McNeil and Brown, 1994; Núñez-Montero et al., 2019; Yisong et al., 2019).

Pathogenesis and immunity

Streptomyces spp. may be isolated from various clinical specimens, but they rarely represent true infections, particularly in a polymicrobial setting. Except of specimens from actinomycotic mycetoma, the isolation of this genus from clinical specimens is frequently considered as contaminants or colonizers (McNeil and Brown, 1994). To diagnose true *Streptomyces* infections is need to relate the clinical manifestations of the infection with the isolation of the organism from sterile sources (better in large quantities), direct microscopic identification in infected tissue with the exclusion of other pathogens or other causes (Kapadia et al., 2007). With at least of two of these criteria, the diagnosis true infection by *Streptomyces* could be done as occurred in the pneumonia case reported by Ariza-Protá et al., where *S. atratus* reached a pure and high growth (4×10^6 colony-forming units per mL) in the quantitative cultures of bronchoalveolar lavage (BAL) specimens and in two blood cultures (Ariza-Protá et al., 2015).

Diagnosis, identification, and typing

Some features of *Streptomyces* spp., as long filamentous gram-positive bacteria that grow aerobically and are negative for partial acid-fast stain, distinguish them from other morphologically similar genera within actinomycetes. In addition, the appearance as a hairball or a mesh of filaments in their culture (Fig. 2J–K) suggested the presence of this genus (McNeil and Brown, 1994). The characterization and systematics of the high number of species belonged to the *Streptomyces* genus has been developed from a large morphology-based classification system (spore color, spore surface ornamentation, morphology of the sporophores) with the evaluation of phenotypic traits. To clarify the confused state of the *Streptomyces* taxonomy, cooperative projects such as the International *Streptomyces* project (ISP) have been done with type strains (Anderson and Wellington, 2001).

The identification at genus level is reached by the use of 16S ribosomal RNA gene sequencing, providing presumptive species identification. For well supported *Streptomyces* clades, there are a good correlation among phylogeny based in 16S rRNA and morphological properties or phenotypic numerical taxonomy studies (Labeda et al., 2012). With a breakpoint score of 99.6% (Clinical and Laboratory Standards Institute, 2008) for the specie assignment, the minor and single membered clusters were considered to be species and the major clusters species-groups. For instance, the largest cluster is considered for the *S. albidoflavus* species-group. However, there is insufficient variation in the sequence of the *rrs* gene within species to perform an accurate species identification or to clarify relationships between close related species or established clades (Labeda et al., 2012). As occur for *Streptomyces griseus* 16S clade, one of the most taxonomically complex group and most prolific in the production of bioactive secondary metabolites (Guo et al., 2008).

In this way, the phylogenetic study of the family *Streptomycetaceae* based on sequences of the 16S rRNA gene showed that several species (*Streptomyces almquistii*, *Streptomyces flocculus*, *Streptomyces gibsonii* and *Streptomyces rangoonensis*), are very closely related phylogenetically to *Streptomyces albus* subsp. *albus*, the type species of the genus. The high similarity of 16S rRNA sequences among

Streptomyces species weakens the statistical support for the backbone structure of their phylogenetic tree. To avoid these issues other ribosomal genes (23S rRNA or 5S rRNA) or intergenic 16S-23S rRNA spacer regions together with other phenotypic and genotypic characters had been used (Anderson and Wellington, 2001). A preliminary study tries to postulate MALDI-TOFF MS as efficient first-line step for rapid identification of *Streptomyces* isolates (Loucif et al., 2014). But, the application of a scheme of multi-locus sequence typing (MLST) with the concatenate of the partial sequences of five house-keeping genes [ATP synthase F1 β -subunit (*atpD*), DNA gyrase B-subunit (*gyrB*), recombinase A (*recA*), RNA polymerase β -subunit (*rpoB*), and tryptophan synthase, β -subunit (*trpB*)] (Guo et al., 2008) is being more efficient to the study of the complex systematic of the taxa of the *Streptomycetaceae* family at inter- intra-species level, showing higher bootstrap support for the different clades than 16S rRNA (Labeda et al., 2012). The coexistence of homologous recombination and ecological divergence has been revealed in the evolution of streptomycetes (Andam et al., 2016; Cheng et al., 2015). By this way, phylogenies of some of the *Streptomyces* species and their ancestry have been studied (Andam et al., 2016). As mentioned above, *Streptomyces* genome is now one of the most highly sequenced. The study of some of these genomes has demonstrate that ecological adaptation promotes genetic differentiation in *S. albidoflavus*, suggesting a model of ecological speciation with gene flow in streptomycete (Li et al., 2019; Yisong et al., 2019).

Some species as been described as responsible of different types of truly human infections such as *Streptomyces albus*, *Streptomyces anulatus*, *Streptomyces atratus*, *Streptomyces bikiniensis*, *Streptomyces coelicolor*, *Streptomyces griseus*, *Streptomyces lanatus*, *Streptomyces lavendulae*, *Streptomyces paraguayensis*, *Streptomyces pelleteri*, *Streptomyces rimosus*, *Streptomyces somaliensis*, *Streptomyces thermovulgaris* and *Streptomyces violaceoruber*. In many cases, the definitive identification could be not possible as occur for *Streptomyces maritimus* vs. *Streptomyces olivaceus*, *Streptomyces nobilis* vs. *Streptomyces parvulus*, *Streptomyces humidus* vs. *Streptomyces pilosus*, *Streptomyces indigoferus* vs. *Streptomyces herbaricolor*. Or only it could be reached at genus level as *Streptomyces* spp. (Kapadia et al., 2007; Riviere et al., 2012; Joseph et al., 2010).

Clinical and epidemiologic features of *Streptomyces* infections

Streptomyces species are a common cause of actinomycetoma or mycetoma, a chronic suppurative infection of the skin and underlying soft-tissue and bone, characterized by tumefaction and draining sinuses. If lower extremity is affected, it is known as Madura foot. *Streptomyces* being frequent in those mycetomas affecting head and neck (McNeil and Brown, 1994; Kapadia et al., 2007). This entity is more prevalent in some areas of Africa and Asia. *S. somaliensis* is one of the major bacterial implicated agents (Develoux et al., 2003), together with *Actinomadura madurae* (van de Sande, 2013; Siddig et al., 2019), with the descriptions of new *Streptomyces* species (Quintana et al., 2008). Mycetoma infection is usually established after a disruption of mucosa through abrasion or traumatism, facilitated by the collagenase activity to access into deeper tissues.

Streptomyces species are rarely known to cause invasive infections (Kapadia et al., 2007), as it is seen in Table 3. But, severe infections as pneumoniae (Kofteridis et al., 2007; Riviere et al., 2012), lung nodules (Kapadia et al., 2007) bacteremia (Moss et al., 2003; Ekkelenkamp et al., 2004), brain abscess (Rose 3rd et al., 2008), endocarditis of the prosthetic valve (Mossad et al., 1995), arthritis, lymphadenitis, pericarditis and peritonitis (Dunne et al., 1998), cervical lymphadenitis, intraspinal mycetoma, and otitis media have been described. In some reported cases of bacteremia the acquisition source was catheter, prosthetic valve, intravenous infusion, primary lesion in internal organs (Ariza-Protá et al., 2015) or a subcutaneous actinomycetoma (Joseph et al., 2010) have been reported. Sometimes, the specific histological description of *Streptomyces* infection shows the presence of sulfur granules (Dunne et al., 1998). In *Streptomyces* pneumonia, the chest X-ray revealed a right lung basal alveolar infiltrate and a reticular interstitial pattern at the lung bases (Fig. 8) (Ariza-Protá et al., 2015).

These infections were mainly considered to be limited patients with immunosuppression linked to malignancies or antineoplastic chemotherapies (Moss et al., 2003), acquired immunodeficiency syndromes, AIDS (Dunne et al., 1998), Cushing Syndrome (Ataiekhorsgani et al., 2014), Crohn's disease, the presence of central venous catheter (Carey et al., 2001) and prosthetic heart valve (Ghanem et al., 2007), treatment with immunosuppressive and oral or inhaled glucocorticoids (Kapadia et al., 2007), and pregnancy (Joseph et al., 2010). But, some studies have report respiratory infections in immunocompetent patient (Kofteridis et al., 2007; Ariza-Protá et al., 2015). Depends on the underlying disease associated with *Streptomyces* infection, exitus could be produced. However, if antimicrobial susceptibility testing is carried out and treatment length recommendations is followed, death linked to *Streptomyces* infection is not produced (Riviere et al., 2012). In any case, if *Streptomyces* infection occurred in patients, immunosuppression status should be suspected.

Similar to humans, susceptible animals can suffer *Streptomyces* infections such as actinomycotic mycetoma (Walton et al., 2015). Plant pathogenicity is rare in this genus, nevertheless dozen or so species, cause important crop diseases in potato, carrot, radish, beet and other tap root crops. The potato common scab, characterized by lesions that form on the potato tuber surface, is produced mainly by *Streptomyces scabies* and *Streptomyces europaieiscabiei* (Wanner, 2009). A family of phytotoxins called the thaxtomins which function is cellulose synthesis inhibitors are the responsible of the plant pathogenicity enhanced with other traits with predicted function is the suppression of plant defense responses. These diseases have had a significant impact on agricultural economies throughout the world. However, beneficial roles have been described as the tripartite mutualism between *Streptomyces* from rhizosphere and flowers, strawberry plants and pollinating bees. Where *Streptomyces* protect both against phytopathogenic fungus and pathogenic bacteria (Kim et al., 2019). Similar to do *Streptomyces* isolates from soils surrounding the nests of termite colonies (Chouvinc et al., 2018).

Table 3 Epidemiologic and clinical characteristics of cases of invasive infection with *Streptomyces* species in the first two decades of the 21st century.

Antimicrobial susceptibility and therapy

There are no standard guidelines for optimal therapy of invasive *Streptomyces* infection. Because the low number of reported cases of *Streptomyces* infections restricts their clinical management, mainly respect to the best choice and length of the antimicrobial treatment. Due to its slow growing nature is need a prolonged treatment period of 6–24 weeks, or 1 year of length (Ameen and Arenas, 2009; Kofteridis et al., 2007; Riviere et al., 2012). The different in vitro susceptibility studies which included different species showed consistent susceptibility to aminoglycosides (amikacin), frequent susceptibility to imipenem, macrolides, and minocycline, and infrequent susceptibility to ampicillin, ciprofloxacin and trimethoprim-sulfamethoxazole (McNeil et al., 1990; Kapadia et al., 2007). As antibiotic-producing bacteria, *Streptomyces* species have self-resistance mechanisms to protect themselves from the attack of their own antibiotics, avoiding suicide (Ogawara, 2016). In this way, it has been described in *S. clavuligerus* the presence of penicillin-binding protein PBPs in both sides of the clavulanic acid/cephamycin gene production cluster and the β -lactamase expression before the production of β -lactams (Coque et al., 1993). For a successful treatment of *Streptomyces* infection, the antimicrobial treatment choice should be based on the specific *in vitro* susceptibility profile of the isolated strain. But, some factors as patient immune status, location of the infection and response to treatment could be modified and guided the treatment (Kapadia et al., 2007).

Bioactive secondary metabolites production

Actinobacteria constitutes the most outstanding group of microorganisms for the production of bioactive compounds, producing nearly 40% of the bioactive secondary metabolites. From them, the genus *Streptomyces* produces nearly 80%. It had been predicted that less of 10% of their bioactive metabolite have been discovered. This ability relies on their genomic potential, a large number of biosynthetic gene clusters (25–70 BCGs) which encode for the enzymes involved in peptide assembly, regulation, resistance, and synthesis of a secondary metabolites. These BCGs include genes encoding for polyketide synthases (PKS), non-ribosomal peptide synthetases (NRPS) and ribosomally synthesized and post-translationally modified peptides (RiPPs) (Belknap et al., 2020; Kloosterman et al., 2020). A large diversity of structurally distinct compounds with variety of biological properties is produced by over 900 species of *Streptomyces*. *Streptomyces* species are considered as antibiotic factories (Barka et al., 2015), being responsible for the production of more the half of all known antibiotics like tetracyclines, chloramphenicol, streptomycin, and clavulanic acid, among others compounds. The genus is also a bountiful source of antiviral, antifungal, antiparasitic, antitumor, immunostimulatory, immunosuppressive, anti-hypertensive agents producers, as well as of bioherbicides (Barka et al., 2015; Watve et al., 2001). The great and diversified biosynthetic potential of this genus is steadily explored to discover new active compounds.

Other aerobic actinomycetes

Actinomadura

The genus *Actinomadura* is one of the member of the family *Thermomonosporaceae* (Lechevalier and Lechevalier, 1970). At the time of writing, 69 species are validly published with a correct name, being the *Actinomadura madurae* the type specie (Parte et al., 2020). Its microscopy and colonial morphologies resembles to those of the *Streptomyces* genus (Conville and Witebsky, 2015). This genus has, a median G–C% content about 70%, with median total length of 9.0 Mb. Nearly to 150 genome assemblies of 41 species are available. *Actinomadura* spp. are common soil-borne organisms that may have a role in the decomposition of organic material. Members of this genus can cause the development of a mycetoma, a term used to describe the clinical nature of the infection and not the causative agent (McNeil and Brown, 1994). Mycetoma refers to localized chronic infections of the skin and underlying tissues indicated by pyogranulomatous inflammation adjacent to the bacteria or fungus. As a result, the infected areas become swollen, often with the development of a draining fistula. Depends of the causative agent aerobic actinomycete or fungus, it is described as actinomycetoma or eumycetoma, respectively. Infection typically mainly results from skin trauma contaminated, via a thorn prick, a wood splinter or a stone cut, with environmental material (e.g., dust, soil, or vegetable matter) enabling enter to the human body (Nenoff et al., 2015; Zijlstra et al., 2016). Different *Actinomadura* species together with *N. brasiliensis* and *N. asteroides*, and *Streptomyces somaliensis* are described as the main responsible agents of actinomycetoma (Cárdenas-de la Garza et al., 2020).

Species reported as human pathogens include *Actinomadura bangladeshensis*, *Actinomadura madurae*, *Actinomadura mexicana*, *Actinomadura pelletieri*, *Actinomadura sputi*, or *Actinomadura vinacea* in cat. Among them, to note *A. madurae* followed by *A. pelletieri* as the most prevalent species in the actinomycetoma (Quintana et al., 2008; Yassin et al., 2010; Mencarini et al., 2016; Bérot et al., 2019; Cárdenas-de la Garza et al., 2020; Bessis et al., 2020; Siddig et al., 2021). There is a limited information regarding in the infections caused by *Actinomadura*, and rarely implicated in other types of infection different to mycetoma. But, intracranial granuloma caused by *A. pelletieri* (Samson et al., 2005), peritonitis by *A. madurae* (Wüst et al., 1990), and pneumonia (Bär et al., 2003) have been reported.

The diagnosis of mycetoma is mainly based on clinical characteristics and microbiological identification of the causative agent. Clinical diagnosis is characterized by a symptomatic triad: a subcutaneous mass (tumefaction), draining sinuses and grain discharge. Spontaneous drainage and manually expressed material from sinus should be carefully examined macro and microscopically to visualize the grains (Izri et al., 2020). The atypical round to irregular cells and the degree of pleomorphism including the large, multinucleated giant cells on cytology were concerning for a neoplastic cellular population. Surgical biopsy, including

Fig. 8 Community-acquired bacteremic *Streptomyces atratus* pneumonia in an immunocompetent adult. (A) Posteroanterior chest X-ray of the right lower lobe with alveolar infiltrate and a reticular interstitial pattern at the lung bases; (B) Chest computed tomographic scan showing right lower lobe alveolar consolidation with minimal pleural effusion, severe bilateral diffuse emphysema, and signs of chronic bronchitis (Ariza-Prata et al., 2015). Courtesy of BioMed Central Ltd. Ariza-Prata et al. (2015) Community-acquired bacteremic *Streptomyces atratus* pneumonia in an immunocompetent adult: a case report. *Journal of Medical Case Reports* 9: 262. <https://doi.org/10.1186/s13256-015-0753-y>.

special stains, confirmed that the origin of the wound was secondary to an infectious and inflammatory nature rather than a neoplastic process. These findings are clinically significant since treatment and prognosis are drastically different between an underlying infectious agent and a neoplastic process, and also between the responsible organism. Actinomycetoma is usually more aggressive than eumycetoma, spreading more quickly and with a greater tendency to be extrapedal than eumycetoma (Zijlstra et al., 2016). The grain appearance, the hematoxylin and eosin stain of tissues, Ziehl-Neelsen stain, cytopathological techniques, the microbiological culture (colonies with different morphology) (Fig. 2L), biochemical test, MALDI-TOFF, and genetic targets (by restriction fragment length polymorphism or by sequencing) allows the definitive diagnosis of the mycetoma entity (Siddig et al., 2021). Among the latter, the sequencing of the 16S rDNA gene of the bacterial DNA in the grains isolated from the patient or in growth cultures is the main choice (Salipante et al., 2013).

Mycetoma is a major health problem in many tropical and subtropical areas, which is noted for social stigmatization. The World Health Organization (WHO) included mycetoma as a neglected tropical disease in 2016. The distribution of the mycetoma causative agents is not equal around the globe. It is commonly observed in the barefoot walking population of tropical and subtropical regions in a zone, known as the "Trans-African or Mycetoma belt" (latitudes 15 degrees south and 30 degrees north) with dry and arid climates. In overall, actinomycetoma is more commonly found in Middle and South-America while eumycetoma is more commonly found in Africa. But within a country, this could also differ per region (van de Sande, 2013). Most cases of actinomycetoma were reported from North African countries (Morocco, Tunisia), but occur, e.g., in Senegal and Sudan, too. They are endemic in Middle and South America (Mexico, Venezuela, Colombia, Argentina) and some cases are reported from Asian countries (India, Laos) (Zijlstra et al., 2016). Rarely, mycetomas were described in the Mediterranean or South East countries of Europe, or in the EUU. The cases of this zone are uncommon and usually imported by migrants from endemic areas (Mencarini et al., 2016). There is an association of mycetomas to distinct species of fungi and actinomycetes in the environment, depending on the concrete amount of rainfall, temperature and humidity (Cárdenas-de la Garza et al., 2020).

The typical clinical presentation of mycetoma is a painless subcutaneous mass of slow progression forming multiple sinuses that drain pus and clusters of bacterial and fungal structures called "grains". The host's inflammatory response consists of a neutrophilic infiltrate and the formation of granulomas that typically contain grains. Single or multi-fistulized pseudotumor appears in the mycetoma. The grains can vary in size, color, and consistency, depending on the etiological species. Untreated infections will eventually destroy the tissues, including muscles and bones (Izri et al., 2020). The most frequent radiological finding in mycetoma is soft tissue swelling followed by bone sclerosis, bone cavities and periosteal reaction (Figs. 9 and 10) (Izri et al., 2020). The mycetoma is usually painless and processes slowly, over months and years. Although mycetoma could be painful in case of secondary bacterial infection.

Mycetoma, a neglected infection of the poor, is considered occupational disease of individuals who work in rural areas, such as farmers or agricultural workers, gardeners, shepherds, construction workers, housewives, or that engage in activities related to the environment, with or without previous trauma (Cárdenas-de la Garza et al., 2020). Mycetomas is more prevalent in people between 20 and 40 years old, with a low socio-economic level, and it is more common in men rather than women (3:1). This infection occurs mostly in the lower extremities of the body, particularly in the feet but other parts of the body can also be involved. In immunocompetent patients dissemination or a generalized invasive mycetoma infection will be prevented. In case of malnutrition or undernourishment and associated illnesses (e.g., malaria, HIV/AIDS, leishmaniasis, diabetes mellitus, etc.) with immunodeficiency, a more intense and faster progression of the disease takes place and exitus may occur (Nenoff et al., 2015).

Similar clinical manifestations appearing in actinomycetoma and eumycetoma, but therapy differs depending of causal microorganisms. Eumycetoma treatment primarily relies on wide surgical excision of the lesion and administration of antifungal agents, while actinomycetoma therapy is based on antimicrobials. The cure rate of patients with *A. madurae* and *A. pelletieri* was up to 80% (Siddig et al., 2020). Sulfonamides, particularly trimethoprim-sulfamethoxazole (TMP/SMX) is the mainstay therapy, often in combination with other drugs such as amikacin or amoxicillin/clavulanic acid. Being the combination of TMP/SMX plus amikacin which provides a higher cure rates (90%) (Cárdenas-de la Garza et al., 2020). Since antibiotics have a difficult time penetrating the dense granulomatous tissue associated with these lesions, the treatment is time extended (weeks, months, sometimes years). Moreover, therapy continues after the resolution of clinical disease. The average length of treatment can vary according to the involved species: *A. madurae* (24 months), *A. pelletieri* (16 months), and *A. mexicana* (6–9 months) (Siddig et al., 2020). The role of surgery varies with the progression of the disease and the inadequate response to chemotherapy (Welsh et al., 2014). As consequence of the significant clinical presentations and complexity in therapeutic implications, the disease diagnosis in the early stages is of high importance. But, mycetoma is mostly a painless infection leading to delayed medical consultation, and aggressive therapies, like amputation of affected body members, and causing consequently lifelong disability.

Gordonia

Proposed *Gordonia* as a new genus by Tsukamura (1971), some representatives were transferred to *Rhodococcus* genus, being returned to *Gordonia* genus through 16S rRNA analysis (Stackebrandt et al., 1988). After, the etymologically correct name of *Gordonia* replaced the previous. At present, the genus *Gordonia* included 44 validly published species, being *Gordonia bronchialis* the type species. It forms the *Gordoniaceae* family together with the *Williamsia* and *Jongsikhunia* genera (Parte et al., 2020). *Gordonia* is arylsulfatase-negative, weakly acid-fast bacilli, non-motile, short rods or circular, with G + C content from 63% to 69% and with a chromosomal size of 4.3–5.6 Mbp. More than 200 genome assemblies of 38 species are available for their study.

Some *Gordonia* species produce pigmented colonies with colors of orange to orange-red and shiny surfaces (Fig. 2O-P) (McNeil and Brown, 1994). Morphological differences are seen as *Gordonia sputi* colonies are smooth, mucoid, and sticky on the medium, whereas *G. bronchialis* colonies are large and dry. This genus does not produce aerial hyphae, except for *Gordonia amarae* and *Gordonia defluvi* (Arenskötter et al., 2004). Plasmids can be detected in some *Gordonia* species from clinical and environmental source (Lee et al., 2020).

Gordonia species have been isolated from various native biotopes such as soil or mangrove rhizosphere, from extensively industrially influenced habitats such as oil-producing wells or hydrocarbon-contaminated soil, from artificial sources such as wastewater treatment bioreactors or biofilters, and from human diseases (Arenskötter et al., 2004). But also this soil bacteria has been isolated from the intestinal contents of mammals (Gil-Sande et al., 2006). As other actinomycetes, *Gordonia* spp. is transferred through aerosols from environmental sources to the respiratory tract.

The major human pathogens in the *Gordonia* species are *G. sputi*, *G. bronchialis*, *Gordonia polyisoprenivorans*, and *Gordonia terrae*. But, other species as *Gordonia aichiensis*, *Gordonia amicalis* (Lai et al., 2012), *Gordonia aarii*, *Gordonia effuse*, *Gordonia otitidis*, *Gordonia rubropertincta*, *Gordonia westfalica* (Gueneau et al., 2020) are also responsible of human infections (Blaschke et al., 2007; Johnson et al., 2011; Ramanan et al., 2013; Akrami et al., 2017; Andalibi and Fatahi-Bafghi, 2017).

Infections caused by *Gordonia* spp. are difficult to diagnose (Fang et al., 2017). This underdiagnosis is due to its slow growth (72 h), the misidentification with other medically important aerobic actinomycetes (*Nocardia* spp. or *Rhodococcus* spp.) by phenotypic test (Gil-Sande et al., 2006), and the role of this environmental bacteria as cause of true infection. Often, the obtained results by biochemical test for species assignment are inconclusive (Andalibi and Fatahi-Bafghi, 2017; Eribi et al., 2020). And in some occasions, MALDI-TOF does not resolve the species (Teng et al., 2018). So, molecular methods as the 16S rRNA gene, *gyrB*, and *secA1* sequencing provide definitive identification of *Gordonia* species (Kang et al., 2009; Lam et al., 2015; Andalibi and Fatahi-Bafghi, 2017; Ding et al., 2017). For typing purpose, these targets are useful together with *hsp65* PCR-RFLP and pulsed-field gel electrophoresis (Johnson et al., 2011; Wright et al., 2012).

A wide spectra of infections are produced by *Gordonia* species (Lai et al., 2010; Andalibi and Fatahi-Bafghi, 2017) as central venous-catheter related bacteremia (Blaschke et al., 2007; Ramanan et al., 2013), pneumonia (Ding et al., 2017), endocarditis (Verma et al., 2006), meningitis (Martín et al., 2017), brain abscess (Eribi et al., 2020), ventriculitis (Blaschke et al., 2007), cutaneous infection (Lai et al., 2012), actinomycetoma (Gueneau et al., 2020), breast abscess, ocular infections (Fang et al., 2017; Choi et al., 2019), pleural infections (Johnson et al., 2011), otitis, arthritis, osteomyelitis, peritonitis (Lam et al., 2015), and surgical site infections (Akrami et al., 2017). Sternal wound infections are caused mainly by *G. bronchialis* (Johnson et al., 2011), being also responsible of two outbreaks, wherein nurse scrub were identified as the vector for contamination of the surgical wounds (Richet et al., 1991; Wright et al., 2012).

Susceptible patients to suffer *Gordonia* infections are those ones with immunocompromised status due to congenital or acquired immunodeficiencies (AIDS infection, hypogammaglobulinemia, leukemia, solid organs cancer, transplant recipients, Hodgkin's disease, etc.), or other underlying diseases chronic hepatitis B virus infection, diabetes mellitus, chronic obstructive pulmonary disease, vasopressor medication, obesity (Blaschke et al., 2007; Johnson et al., 2011; Guerrero et al., 2014; Kempf et al., 2004; Ding et al., 2017). However, many reported cases occurred in immunocompetent patients, being the main risk factor the presence of foreign bodies including central lines and shunts (Blaschke et al., 2007; Lai et al., 2010; Bartolomé-Álvarez et al., 2016; Akrami et al., 2017). This event is in relation with the ability of some *Gordonia* species to attach and colonize the surface of medical devices by biofilm formation, leading to bacteremia. For instance, *G. polyisoprenivorans* produces biosurfactants that help to form biofilm onto the catheter decreasing antibiotic penetration (Verma et al., 2006).

There is not a standardized treatment for *Gordonia* infections, and little is the information about susceptibility. Fortunately, in contrast to some other actinomycetes, *Gordonia* are generally susceptible to many antimicrobial drugs. Amoxicillin-clavulanic acid, ceftriaxone, carbapenems, aminoglycosides, linezolid and fluoroquinolones showed better activity against *Gordonia* species than macrolides and trimethoprim-sulfamethoxazole (Blaschke et al., 2007; Moser et al., 2012; Bartolomé-Álvarez et al., 2016). Frequently, patients are treated with a variety of antimicrobial regimens, usually for several weeks or months, with good outcome in most cases (Guerrero et al., 2014; Ding et al., 2017). Being the prognosis for *Gordonia* bloodstream infections is variable, depending on the underlying conditions of the host, the clinical factors related to the infection, and the time to diagnosis. For catheter-associated *Gordonia* infections, catheter removal is a common practice. Depend on infection type and its evolution, surgical debridement could be required.

Gordonia is a bacteria potentially useful for environmental and industrial biotechnology, because of their abilities to degrade xenobiotics, environmental pollutants, or biodegradable natural polymers as well as to transform or synthesize possibly useful compounds (Arenskötter et al., 2004; Drzyzga, 2012).

Tsukamurella

According to the current state of the taxonomy, *Tsukamurella* (Collins et al., 1988) is the single genus of the family *Tsukamurellaceae*, which is composed of 16 validly identified species being *Tsukamurella paurometabola* the type species (<https://lpsn.dsmz.de/family/tsukamurellaceae>) (Parte et al., 2020). *Tsukamurella* is a partially acid fast, obligatory aerobic bacterium that does not have an aerial hyphae. It is a non-spore forming and non-motile bacterium with rod-shaped cells that can be straight or curved and can be seen in pairs or groups of coccobacillary forms by Gram stain. Some *Tsukamurella* species produce pigmented colonies (Fig. 2Q–R) (Safaei et al., 2018). This genus possess a circular chromosome with a G + C content close to 70% and a size range 4.6–5.2 Mbp (Teng et al., 2016). A limited number of genomes assemblies are available.

Tsukamurella spp. is environmental saprophyte which is isolated from different environmental sources (soil, water, sludge, foam) as well as in animals (arthropods, sponges, snakes). The *Tsukamurella* species involved in human infections have been: *Tsukamurella incheonensis*, *T. paurometabola*, *Tsukamurella strandjordii*, *Tsukamurella tyrosinosolvens*, *Tsukamurella pulmonis*, *Tsukamurella hongkongensis* and *Tsukamurella sinensis* (Yassin et al., 1996, 1997). Incorrect species identifications via MALDI-TOF were due to the absence of the corresponding reference spectra in the database (Teng et al., 2016). The most commonly used molecular method for bacterial identification, 16S rRNA gene sequencing is probably not discriminative enough to provide a species-level identification of *Tsukamurella* spp. differing with less than 1% among them. In contrast, *secA1* gene appears to be a better and more reliable target to discriminate *Tsukamurella* species (Bernal and Balbin, 2017). The phylogenomic analyses, concordant to the clustering patterns observed in phenotypic and MALDI-TOF MS analyses, reclassified some species (*T. spongiae* as *T. pulmonis*, *T. carboxydivorans* as *T. tyrosinosolvens*, and *T. sunchonensis* as *T. pseudospumae*) (Teng et al., 2016).

They are opportunistic pathogens and can be spread through clinical instruments (e.g., catheters) resulting in sporadic episodes of nosocomial infections. So, the most common *Tsukamurella* infections in human are related to the presence of indwelling devices. They therefore can cause various infections in humans, such as respiratory tract infection, meningitis, brain abscess, bacteremia,

endocarditis, catheter related bloodstream infection, peritonitis, conjunctivitis keratitis, cutaneous infection, and acute otitis media (Teng et al., 2020; Safaei et al., 2018; Ismayilov et al., 2020; Malik et al., 2020). *T. tyrosinosolvens* was the most common species encountered in patients with *Tsukamurella* infections (Leroy et al., 2020).

Susceptible patients for *Tsukamurella* infections are mainly patients with immunosuppressive diseases, renal failure, and foreign bodies (e.g., clinical equipment). In immunocompromised patients, mostly with hematology malignancies, the bacteremia's length was often notably long, up to 4 weeks. The leading causes of persistent bacteremia were noticed: the time to positivity of the bacterial vial; the frequent consideration of Gram-positive bacilli rods as possible contaminant microorganisms; and the time required reaching an accurate bacterial identification that might have led to inappropriate empirical antibiotic choices (Leroy et al., 2020).

The antibiotic susceptibility profile of different *Tsukamurella* species remains poorly reported. The best antibiotic susceptibility testing is microbroth dilution. *Tsukamurella* spp. are resistant to penicillin, oxacillin, piperacillin/tazobactam and cephalosporins, which are prescribed for treatment of nontuberculous mycobacteria infection. Whereas *Tsukamurella* is susceptible to amikacin, ciprofloxacin, imipenem, doxycycline, linezolid and sulfamethoxazole. But, susceptibility testing is necessary for proper treatment of *Tsukamurella* infections. Effective results resulted from a combination of β -lactam or macrolide with aminoglycoside antibiotic agents for a long treatment period. In addition to optimal antibiotic treatment, probably to be defined due to the limited number of isolates reported, catheter removal seems to be the cornerstone of the treatment (Safaei et al., 2018; Leroy et al., 2020).

Introduction

Anaerobic bacteria are the most numerous components of the normal human microbiota colonizing the mucous membranes. They are dominant commensals in mucosal surfaces such as the oral cavity and the gastrointestinal and female genital tracts. In some circumstances, especially after the breakdown of mucosal barriers, these microorganisms may spread from indigenous microbiota into normally sterile body sites and they can be responsible for severe disease like in blood infections. The presence of anaerobic microorganisms predominates in several clinical syndromes, and this fact could be attributed to the large numbers of these bacteria residing on mucous membranes, the production of a wide variety of virulence factors, the synergy with other aerobic bacteria and the increased resistance of these microorganisms to some antimicrobials. However, most clinically significant anaerobes are involved in mixed infections alongside aerobic bacteria.

Infections due to anaerobic isolates may sometimes be missed because of the special measures required for their transportation. Other critical factors for the successful isolation of these microorganisms in the microbiology laboratory include incubation in anaerobic atmosphere, the use of specialized culture media, and prolonged culture (Finegold, 1995). Moreover, several infections caused by anaerobes are important due to the fact of the observation of higher resistance rates of these microorganisms to some antimicrobial agents over the last years (Brook et al., 2013). The combination of all those factors makes it crucial to know when an anaerobic infection is vital in order to use appropriate microbiologic methods to identify the bacteria and to select the correct treatment.

This chapter focuses on the description of the main genera of anaerobic bacteria that causes human infections and their main syndromes in which they are implicated (Table 1).

Table 1 Main anaerobic bacteria and clinical syndromes in human population.

Type of bacteria	Microorganism	Infectious syndrome
Gram-negative bacilli	<i>Bacteroides</i> spp.	Abdominal infections, peritonitis, bacteremia, genital infections, abscess
	<i>Porphyromonas</i> spp.	Orofacial infections
	<i>Prevotella</i> spp.	Orofacial infections, periodontitis, abdominal infections, genital infections, bacteremia
	<i>Fusobacterium</i> spp.	Cerebral abscess, bacteremia, orofacial infections, pneumonia, Lemière syndrome
Gram-positive bacilli	<i>Clostridium</i> spp.	Bacteremia, skin and soft-tissue infections, diarrhea (colitis pseudomembranous), necrotizing enterocolitis, tetanus, botulism
	<i>Actinomyces</i> spp.	Cerebral abscess, mastoiditis, genital infections, neck and head infections, lung infections
	<i>Cutibacterium acnes</i>	Medical devices infections
	<i>Bifidobacterium</i> spp.	Cervical lymphadenitis, abdominal infections, periodontitis
	<i>Eubacterium</i> spp.	Periodontitis, odontogenic abscess, bite infections
Gram-positive cocci	<i>Finnegoldia magna</i> , <i>Parvimonas micra</i> , <i>Peptoniphilus</i> spp., <i>Anaerococcus</i> spp., <i>Peptostreptococcus</i> spp.	Skin and soft-tissue infections, abdominal infections, abscess, bacteremia
Gram-negative cocci	<i>Veillonella</i> spp.	Polymicrobial infections, bacteremia

Anaerobic bacteria present in the human microbiota

Human microbiota is integrated by different kind of microorganisms of which anaerobic bacteria are the most frequent of them (Huttenhower et al., 2012). Until now, culture of specimens has been the gold standard of microbiology for the characterization of microorganisms that make up the microbiome. However, many of the bacteria isolated from these samples were no cultivable, as it was demonstrated in a study (Gill et al., 2006). Today, new techniques based on DNA analysis are being used in order to characterize new pathogens as well as anaerobic bacteria. Anaerobes are especially present in mucosal surfaces like the gastrointestinal and female genital tract and the oral cavity. The asymptomatic carriage of *Clostridioides difficile* has been confirmed in the human gastrointestinal tract in a small number of healthy people. The number of colonized persons increases during hospitalization and among those who are taking antimicrobial agents. The microbial species and concentrations varies depending on the location; the highest anaerobes concentration is found in the oral mucosa with concentrations ranging $10^2/\text{mL}$ to $10^{12}/\text{mL}$. In the gingival area, the anaerobe:aerobe ratio is 1000:1. The main anaerobic microorganisms present in this location are species of the genera *Prevotella*, *Porphyromonas*, *Fusobacterium* and *Bacteroides*.

Regarding to the microbiota of the stomach and upper intestine, low number of anaerobic bacteria are present in this area; in persons with decreased gastric acidity, the microbiota of the stomach is similar to those present in the oral cavity. However, the microbiota of the upper intestine resembles those present in the colon. The predominant anaerobes present in this last location are species of *Bacteroides* spp., *Clostridium*, *Peptostreptococcus* and *Fusobacterium*.

Regarding to the normal female genital tract, the ratio anaerobic:aerobic range of 1:1 to 10:1. The predominant anaerobic species are *Prevotella*, *Bacteroides*, *Fusobacterium*, *Clostridium* and *Lactobacillus*. *Bacteroides* spp. is found in the genital tract of approximately 50% of women and supposes a 15% of the microbial population.

Anaerobic microorganisms also may be present in areas that are exposed to air; the skin microbiota contains species of anaerobes such as *Cutibacterium* (formerly *Propionibacterium*) *acnes*, other species of *Cutibacterium* and *Peptostreptococcus*.

Fig. 1 shows macroscopic aspect of some anaerobic microorganisms.

Taxonomic and microbiologic classification

Despite the great number of anaerobes present in the normal human microbiota, only relatively few species are involved in human infections. A significant fact is that infections involving anaerobic pathogens are often polymicrobial and usually are produced as a consequence of the disruption of mucosal surfaces by surgery, trauma, tumors or ischemia and the spread of microbiota to sterile sites.

Anaerobic microorganisms are divided in Gram-negative and Gram-positive and in bacilli and cocci. There are also some Gram variable microorganisms such as *Actinomyces* spp., *Clostridium tetani* and *Cutibacterium acnes*, alternating between a Gram-negative and Gram-positive phase depending on the replication-stationary stage (Beveridge, 1990).

Fig. 1 Microphotographs showing the macroscopic aspect of some anaerobic microorganisms isolated in blood agar: (A) *Bacteroides fragilis*. (B) *Cutibacterium acnes*. (C) *Peptoniphilus hareii*. (D) *Finegoldia magna*.

Gram-negative anaerobic bacilli

Bacteroides, *Prevotella*, *Porphyromonas* and *Fusobacterium* species are the most frequent anaerobes in this group isolated in clinical samples and involved in human infections, especially the *B. fragilis* group (Wexler, 2007). Of this group, *B. fragilis* is the species most often isolated from human infections. Other members of this group include *B. thetaiotaomicron*, *B. ovatus*, *B. vulgatus* and *B. distasonis*. A definitive taxonomic classification of this genus was performed based on the study of 16S rRNA (Paster et al., 1994). These are microorganisms commonly involved in intraabdominal infections and other conditions such as decubitus ulcer and diabetic foot ulcers. Moreover, the disruption of the mucosal barrier becomes in abscess formation and bacteremia. *B. fragilis* virulence is mostly by a toxin production. Enterotoxigenic *B. fragilis* strains secrete a termed enterotoxin and may have a role in inflammatory diarrhea and flare-ups of inflammatory bowel disease (Sears, 2009; Basset et al., 2004).

Prevotella (both pigmented and non-pigmented species) and *Porphyromonas* species are anaerobic Gram-negative bacilli involved in oral cavity infections and also they are the most often anaerobes isolated from respiratory infections and their complications. As a consequence of their presence in infections of the oral cavity, these microorganisms can spread within the intracranial cavity and could produce brain abscesses.

Finally, regarding to *Fusobacterium* species they are mainly part of the microbiota of the oral cavity and the intestinal tract and they are able to produce abscesses and necrotizing infections such as pneumonia and brain infections.

Gram-positive anaerobic bacilli

Among the anaerobic Gram-positive bacilli, *Clostridium* spp. is most commonly isolated from human infections. These microorganisms are usually associated with wound and bloodstream infections and abscesses. There is more than 200 species of *Clostridium*, but the most common species isolated from clinical samples are *C. perfringens*, *C. septicum*, *C. ramnosum*, *C. novyi* and *C. sordellii* (Brook, 2016). *C. difficile* may cause several intestinal diseases that range from mild sickness to severe intestinal infections called pseudomembranous colitis.

Regarding to the anaerobic Gram-positive non-spore-forming rods, these bacteria are part of the microbiota of different body sites like vagina, skin, gingival crevices and gastrointestinal tract. This group include *Cutibacterium* (formerly *Propionibacterium*), *Bifidobacterium*, *Lactobacillus*, *Actinomyces*, *Eubacterium*, *Atopobium* and others. These anaerobes may be isolated from aspiration pneumonia, peritonitis, periodontitis, gynecological infections and intracranial abscesses. *C. acnes* is the most frequent species included in genera *Cutibacterium* and usually has low virulence, but it might cause infections in implanted prostheses and medical devices as well as in central nervous system (CNS) shunts and drains.

Gram-positive anaerobic cocci (GPACs)

Among the GPAC associated with clinical infections, the most prominent isolated bacteria from human samples are *Anaerococcus*, *Finegoldia*, *Parvimonas*, *Peptoniphilus* and *Peptostreptococcus*. GPACs are mostly isolated from polymicrobial infections so their relevance has often been overlooked. Moreover the taxonomy of GPACs has undergone various changes over the years, mainly due to the introduction of new molecular identification methods. These anaerobic bacteria are part of the oral, upper respiratory, genitourinary and intestinal tract and skin microbiota and are isolated from infections such as lung abscesses, aspiration pneumonia, soft tissue infections, female genital tract and chronic sinusitis.

Gram-negative anaerobic cocci

From the three described genera of Gram-negative anaerobic cocci, *Veillonella*, *Acidaminococcus* and *Megasphaera*, the first of them is that it has epidemiological relevance. Its clinical meaning is unknown and they are considered microorganisms of low virulence. The most relevant species are *V. parvula*, *V. atypica* and *V. dispar*, which are part of the microbiota of the oral cavity and the intestinal and genitourinary tract. They are mainly isolated within polymicrobial infections, although in some circumstances such as malignancies may cause bacteremia (Cobo et al., 2020a, b).

Pathogenesis and virulence factors of anaerobic bacteria

Once anaerobic microorganisms are present in tissue with a lowered oxidation-reduction potential, they may proliferate and cause local infection. After this, there are some factors involved in the pathogenesis of these kinds of infections such as bacterial synergy, virulence factors of the bacteria, and mechanism of abscess formation. Some of these virulence factors are showed in Table 2. Virulence factors may contribute to anaerobic infection due to its ability to evade host defenses, produce enzymes and toxins, adhere to cell surfaces and exhibit some surface structures like capsular polysaccharides.

Regarding to the GPACs, in two of them has been possible to identify some virulence factors. The well-described virulence factors of *F. magna* are Protein L (Björck and Protein, 1988), subtilase (SufA) (Karlsson et al., 2007), peptostreptococcal albumin binding protein (PAB) (De Château and Björck, 1994) and *F. magna* adhesion factor (FAF) (Frick et al., 2008).

Protein L induces an effect on human basophils inducing the synthesis of leukotriene C₄ (LTC₄) (Patella et al., 1990). LTC₄ is a proinflammatory mediator that induces a greater histamine release and the synthesis of the prostaglandin D₂. These two mediators have significant importance in inflammation, so expression of protein L is correlated with virulence (Kastern et al., 1990).

Table 2 Main virulence factors of anaerobes.

Microorganism	Virulence factor
<i>Finegoldia magna</i>	Protein L SufA (subtilase) PAB (peptostreptococcal albumin binding protein) FAF (<i>F. magna</i> adhesion factor)
<i>Parvimonas micra</i>	Capsule formation Adhesins Immunoglobulin Fc-binding proteins Gelatinase and protease activity Production of TNF- α and IL-1 β
<i>Bacteroides fragilis</i> group	Hemagglutinin Protease and neuraminidase activity Capsular polysaccharides Enterotoxin production
<i>Prevotella</i> species	Protease production Lipopolysaccharides
<i>Fusobacterium</i> species	Proteases production Lipopolysaccharides Leukotoxin production Hemolysin and phospholipase (<i>F. necrophorum</i>) Adhesins (<i>F. nucleatum</i>)
<i>Porphyromonas gingivalis</i>	Capsule Hemolysin Proteases Lipopolysaccharides

In addition, protein L is a potent inducer of the synthesis and release of IL-4 and IL-13 and classifies this protein as a bacterial super-antigen (Genovese et al., 2003).

Protein PAB is a human serum albumin present in several isolates of *F. magna* whose presence suggests a link between this phenotype and the presence of suppurative infections. Therefore, protein PAB plays an important role in enhancing bacterial virulence during infection.

On the other hand, subtilisin-like proteinase of *F. magna* whose presence may result in enhanced pathogenicity of this anaerobe during the infection. The ability of SufA to cleave and inactivate some antimicrobial peptides might lead to increase survival and proliferation during infection. Moreover, several studies showed that SufA was able to modulate the activity of chemokines to promote bacterial survival during epithelial inflammation decreasing the inflammatory response (Karlsson et al., 2009a). In addition, the role of SufA in the interaction with the host coagulation system was also studied. SufA was found to cleave fibrinogen which affects to fibrin polymerization which prevent the formation of a fibrin network around *F. magna* and to the wound healing that leads to the delay of wound repair (Karlsson et al., 2009b). The final effect is that the bacteria are trapped and this fact facilitates the establishment of infection and the promotion of virulence (Karlsson et al., 2009a).

Finally, the FAF protein is a factor that mediates bacterial aggregation. The presence of this protein in the *F. magna* surface could impair wound healing in chronic wounds. Moreover, this factor was found to have a neutralizing capacity on bacterial proteins such as LL-37, MK and hBD-3 (Frick et al., 2011).

Regarding to *Parvimonas micra*, this is one of the best studied microorganisms belonging to the GPAC group in terms of characterization of its virulence factors. The capacity of capsule formation and the ability to form hydrogen sulfide have been demonstrated to be as important virulence factors (Carlsson et al., 1993). Moreover, *P. micra* have the capacity to adhere to gingival epithelial cells (Dzink et al., 1989) and to express immunoglobulin Fc-binding proteins (Grenier and Michaud, 1994). In addition, some data in several strains of *P. micra* demonstrated to have cell-associated gelatinase activity (Ng et al., 1998) and elastase activity (Mikamo et al., 1999). Finally, some studies also reported the *P. micra* production of TNF- α and IL-1 β which are important determinants of the periodontitis progression (Tanabe et al., 2007).

In Gram-negative anaerobic microorganisms, some virulence factors have been also identified. Regarding to *B. fragilis*, this microorganism has a high ability for abscess formation. *Bacteroides* species have involvement in the prolongation of the intrinsic pathway of clotting in human blood (Murphy et al., 2011). *B. fragilis* and other *Bacteroides* species such as *B. thetaiotaomicron* cause the release of significant levels of bradykinin in human plasma that will provide the bacteria the ability to spread by inhibition of clot formation (Murphy et al., 2011). However, the capsular polysaccharide has been identified as the major virulence factor of *B. fragilis*, playing a central role in the abscess production (Onderdonk et al., 1977). *B. fragilis* may express different surface polysaccharide combinations through a reversible inversion of DNA segments (Krinos et al., 2001). The most important and most studied of these polysaccharides are PSA and PSB; PSA was demonstrated to activate host CD4⁺ T cells and facilitate the release of interleukin-17, interferon- γ , and chemokines (Chung et al., 2003; Wang et al., 2006). Moreover, the capsule promotes the release of the proinflammatory cytokines tumor necrosis factor- α and IL-1 β that are found to potentiate the increase of cell adhesion molecules in order to increase the binding of neutrophils to these cells and initiates abscess formation (Gibson et al., 1998).

On the other hand, *B. fragilis* produces other virulence factors such as fimbriae, pili and hemagglutinin molecules that help in attachment to host cell surfaces. Moreover, they produce several toxins and enzymes like neuraminidase, protease, hydrolase and superoxide dismutase. Enterotoxigenic *B. fragilis* strains secrete an enterotoxin termed *B. fragilis* toxin (BFT) and may have a role in inflammatory diarrhea and flare-ups of inflammatory bowel disease (Basset et al., 2004; Sears, 2009). This toxin has a cytopathic effect for epithelial intestinal cells inducing tissue damage.

On the other hand, *C. difficile* produces two toxins, an enterotoxin (toxin A) and a cytotoxin (toxin B). In some strains a third toxin (binary toxin) could be produced, although the importance in the pathogenesis of this disease has not been clearly established. Apparently, toxins A and B are able to interact synergistically in the pathogenesis of *C. difficile* infection, although toxin-A negative strains can also produce disease. Highly virulent *C. difficile* (BI/NAP1/PCR ribotype 027) strains have caused some outbreaks. These isolates are characterized by high level toxin production due to a deletion in the negative regulator gene (tcdC) of toxin A and B. Other *Clostridium* species produce some toxins such as neurotoxins, enterotoxins, lecithinases, DNAses and others and this fact justify their virulence and involvement in aggressive clinical pictures.

F. necrophorum and *F. nucleatum* produce a numerous types of toxins such as leukotoxin, endotoxin and hemolysin causing several necrotic diseases and oral infections. *F. nucleatum* also co-aggregates with other oral bacteria to increase attachment to plaque helped with some adhesin molecules. Both species of *Fusobacterium* produce a lipopolysaccharide responsible for the production of cytokines and other inflammatory mediators playing a central role in periodontal disease.

Regarding to *Prevotella* species little is known about the virulence factors, although production of proteases and metabolic products has been described, especially IgA proteases. The destruction of Ig A produced by mucosal surfaces permit this anaerobe to evade the first line of defense.

The last Gram-negative anaerobe which is known producing virulence factors is *P. gingivalis*. This bacterium produces proteases that can help to cause attachment, degradation or cleavage of host cell proteins and surface receptors, adhesins and hemagglutinins. The capsular polysaccharide of this microorganism may facilitate the spread of infection because it has a proinflammatory activity implicated in the periodontal disease.

Clinical syndromes associated with anaerobic microorganisms

Anaerobic bacteria are common pathogens in humans and they can produce a great variety of infections in different body locations. Table 3 summarizes the type and location of these infections. Although most clinically significant anaerobes are involved in mixed infections alongside aerobic bacteria, they can be responsible for severe disease in certain circumstances, such as in blood infections or when present in normally sterile body sites. Infections due to anaerobic isolates may sometimes be missed because of the special measures required for their transportation. Other critical factors for the successful isolation of these microorganisms in the microbiology laboratory include incubation in anaerobic atmosphere, the use of specialized culture media, and prolonged culture (Finegold, 1995). The main feature of infection caused by anaerobes is the abscess formation, both in the site of direct bacterial contamination and in distant sites due to contiguous and hematogenous spread.

Central nervous system infections

In this region, the main types of infections in which anaerobic bacteria are involved include subdural empyema and both brain and epidural abscesses. Meningitis caused by anaerobes is quite rare and often suggests a parameningeal collection or shunt infection. However, anaerobic microorganisms are common pathogens producers of brain abscesses (Brook, 2017; Le Moal et al., 2003). This clinical entity is caused by microorganisms belonging to the normal oral cavity microbiota as a consequence of its spread from otitis, sinusitis or oral infections. On the other hand, it is not unusual the hematogenous dissemination from intraabdominal or pelvic infections, leading to the production of infections located at the brain region. In these last circumstances, the microorganisms implicated are those present in the intestinal and/or female genital tract microbiota. The microbiology of these abscesses may include a great variety of pathogens; it may present as an isolated infection by anaerobes or a mixture of aerobic and anaerobic bacteria, being the anaerobic bacteria common constituents of brain abscesses. The main anaerobes implicated in the production of brain abscesses are GPACs, *Prevotella*, *C. acnes*, *Fusobacterium*, *Bacteroides*, and *Actinomyces* (Brook, 2017).

Table 3 Types and location of main infections caused by anaerobic microorganisms.

Location of infection	Infection
Central nervous system	Epidural abscess Subdural empyema Brain abscess

Chest cavity	Pneumonia Pneumonitis (aspiration) Pulmonary abscess
Abdominal cavity	Empyema Intraabdominal abscess Liver abscess Biliary tract infection Peritonitis
Female genital tract	Appendicitis Pelvic inflammatory disease Pelvic abscess Bartholin gland abscess Endometritis Bacterial vaginosis Post-surgery infection
Blood	Bacteremia
Skin and soft tissue	Cutaneous abscess and wound Diabetic foot ulcer Pressure ulcer Gas gangrene
Bone and joints	Arthritis and osteomyelitis

Head, neck and oral cavity infections

Anaerobic microorganisms are involved in some infections of the oral cavity and adjacent tissues. The bacteria isolated from these infections reflect the microorganisms present in the normal oral microbiota, especially *Bacteroides non-fragilis*, pigmented *Prevotella* species, *Porphyromonas*, *Fusobacteria* and *Peptostreptococcus*.

Dental infections

Dental infections include a group of diseases such as periapical or dental abscesses, pulpitis and perimandibular space infections and anaerobes are involved in most clinically important infections in this area. The initial lesion is endodontal and the infection progress to the periapical region and it may spread through the mandible to involve adjacent tissues causing osteomyelitis of the maxillary sinuses and infection of submandibular spaces. Factors involved in this progression are unknown but the presence of gingival microbiome forming a “network of bacteria” may contribute (Siqueira and Rôças, 2013).

Also, in the gingival crevices and gums, anaerobic microorganisms are able to cause gingivitis, periodontitis and periodontal abscesses. Formation of dental plaque influenced by several factors like oral hygiene, leads to overgrowth of pathogenic bacteria and development of infections in this location. The bacteria mainly involved in these kinds of infections are *Prevotella*, *Fusobacterium*, *Porphyromonas* and *Treponema* spp.

The most common type of periodontitis is chronic periodontitis, a major cause of tooth loss. However, gingivitis may become a more serious infection known as Vincent angina or trench mouth. This disease is a necrotizing ulcerative process associated with severe pain, tender bleeding gums, tissue destruction, pseudomembrane formation and putrid discharge. Patients may have fever, cervical lymphadenopathy and leukocytosis. This infection may spread to adjacent tissues causing bone or soft tissue destruction or acute necrosis of the pharynx.

Another necrotizing infection of the oral mucous membranes is noma or cancrum oris. As in the Vincent angina, this infection is characterized by destruction of bone and soft tissue. In the most severe cases, it can evolve quickly to from gingival inflammation to orofacial gangrene (Enwonwu et al., 2006). The majority of cases are encountered in sub-Saharan Africa in young children with malnutrition or systemic disease (Falkler et al., 1999).

Deep neck space infections

The deep neck spaces are formed by fascial planes of the head and neck such as the submandibular space. The infections in these areas often emerge from dental infections rather than from pharynx or tonsils infections.

There is two severe and life-threatening perimandibular infections known as Lemierre syndrome and Ludwig’s angina.

Ludwig’s angina consist of a bilateral infection of the sublingual and submandibular spaces accompanied by marked local tissue swelling (base of the tongue), tongue displacement and potential airway compromise. This disease is typically a polymicrobial infection involving the oral cavity microbiota.

On the other hand, Lemierre’s syndrome is an infection of the posterior compartment of the lateral pharyngeal space with subsequent septic thrombophlebitis of the internal jugular vein, bacteremia and lung metastatic abscesses. This entity is usually caused by *F. necrophorum* but other anaerobic microorganisms such as *Bacteroides*, *Peptostreptococcus*, *Porphyromonas* and *Prevotella* have been involved in this infection (Kuppalli et al., 2012; Klug et al., 2016).

Other infections

Although rare, anaerobic microorganisms are able to produce chronic sinusitis in both adults and children. The predominant anaerobes involved in these infections are *Fusobacterium*, *Peptostreptococcus*, *Prevotella* and *C. acnes*. However, the majority of these infections are caused by mixed infections of aerobic and anaerobic bacteria (Brook, 2008a).

Chest cavity infections

Anaerobic bacteria are relatively common pathogens isolated from infections of the pleuropulmonary area. These infections are predominantly acquired due to aspiration of oral or dental secretions by patients with predisposing conditions such as neurologic disorders, periodontal or gingival disease and/or situations with temporary loss of consciousness (Bartlett, 2012).

The anaerobic microorganisms most commonly associated with pleuropulmonary infections are those that form part of the oral cavity and include *Prevotella*, *Peptostreptococcus*, *Bacteroides* and *Fusobacteria*. However, a great quantity of these infections are mixed anaerobic and aerobic, especially microaerophilic streptococci (Takayanagi et al., 2010; El-Sohl et al., 2003).

Clinical presentation may occur in four ways: aspiration pneumonitis, necrotizing pneumonia, lung abscess or empyema. Aspiration pneumonitis is generally an indolent form of pneumonia in contrast to the abrupt course of acute pneumonia. Patients often present with symptoms of chronic disease, including anemia and weight loss. Initially, patients rarely have putrid sputum although can become malodorous in the later stages of disease. It can see a mixed microbiota in the Gram stain and the infection is produced in a dependent pulmonary segment (Bartlett, 2012). Samples obtained by transtracheal and/or transthoracic aspiration may be adequate for the diagnosis.

On the other hand, necrotizing pneumonia is a complication of the aspiration pneumonitis and is characterized by the presence of many abscesses within the lung parenchyma.

Regarding to the lung abscesses, the majority of them are secondary to the presence of periodontal disease and in these cases the predominant bacteria are those present in the oral microbiota. Finally, empyemas are long-term complications of anaerobic pulmonary infection and are characterized by pleuritic chest pain.

Abdominal cavity infections

The main intraabdominal infections caused by anaerobic microorganisms are the peritonitis, both generalized and localized, and the abscesses. These entities are usually polymicrobial and mixed infections (aerobic and anaerobic bacteria), with a predominance of coliforms, anaerobes and *Streptococcus/Enterococcus*. They accounted due to a break in continuity of the mucosal surface and the leak of the normal intestinal microbiota into the sterile peritoneal cavity. The main causes of the mucosal break are diseases such as neoplasms, diverticulitis, appendicitis, inflammatory bowel disease, surgery or trauma. The majority of bacteria isolated in these kinds of infections are *Escherichia coli* and *Bacteroides* spp., especially *B. fragilis* group. Other anaerobic microorganisms commonly isolated are *Prevotella*, *Peptostreptococcus* and *Fusobacterium* spp. Regarding to the proximal bowel infections, the perforation of this area is followed of infection due to aerobic and anaerobic Gram-positive bacteria and *Candida* spp. Moreover, infections in this region involve other microorganisms like *C. septicum* and other clostridia.

The toxin-producing *C. difficile* is responsible for antibiotic-associated gastrointestinal diseases ranging from a relatively benign, self-limited diarrhea to a severe, life-threatening pseudomembranous colitis. The antibiotics alter the normal microbiota allowing the overgrowth of these relatively resistant microorganisms. The disease is produced due to the proliferation of this bacterium in the colonic mucosa and the production of toxins.

Female genital tract infections

The female genital tract is a body region that constitutes a major reservoir for anaerobic microorganisms. The majority of infections of the female genital tract that are not caused by sexually transmitted agents involve anaerobes. The main infections that can be considered within this section are endometritis, Bartholin gland abscesses, bacterial vaginosis, salpingitis, pelvic cellulitis, septic thrombophlebitis, wound infections, tubo-ovarian abscesses, pyometra, adnexal abscesses and pelvic inflammatory disease, and septic abortion. The main bacteria implicated in these kinds of infections include *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, *Actinomyces*, *Eubacterium* and *Clostridium*. Like in the majority of anaerobic infections, most cases are produced by mixed infections, involving both aerobes and anaerobes (Cereija et al., 2013).

Anaerobic bacteremia

Anaerobic microorganisms remain an important cause of bloodstream infection being still a major cause of morbidity and, despite all the advances in medical practice in recent years, the presence of anaerobes in the bloodstream continues to have a high associated mortality requiring appropriate treatment (Raymond et al., 2006; Blairon et al., 2006). The detection rate of anaerobes in blood cultures is around 0.5–11.8% of all bacteremic episodes, depending on geographic location, and both patient age and condition (Arzese et al., 1995). Mortality from anaerobic bacteremia has remained high over the past few years. Mortality rates reported range from 14% (De Keukeleire et al., 2016) to 27% (Robert et al., 2008). In a very recent report, the mortality rate was 25.7%, similar to other investigations (Cobo et al., 2020a, b). A study obtained a mortality rate of 14% for patients with adequate antimicrobial therapy compared with 63% for patients with inappropriate treatment (Zahar et al., 2005).

Some factors frequently associated with high mortality from anaerobic bacteremia have been published including underlying malignancies, especially hematologic, diabetes and gastrointestinal surgery (Blairon et al., 2006; Lassmann et al., 2007). A below mentioned report (Cobo et al., 2020a, b), moreover, found three variables significantly and independently associated with mortality with anaerobic bacteremia: hospitalization in an ICU, presence of septic shock and presence of any type of cancer.

Most anaerobic bacteriemias are caused by Gram-negative bacilli, especially by members of *B. fragilis* group (60% cases), followed by *Clostridium*, *Peptostreptococcus* and *Fusobacterium* species (Brook, 2010). Some of these bacteriemias could be polymicrobials (Cobo et al., 2018).

Anaerobic bacteremia is often secondary to an infectious process derivate from an intraabdominal, female genital tract, respiratory tract or soft tissue source. Predisposing factors for this infection are mainly debilitating diseases such as malignancies, diabetes, organ transplantation and abdominal and pelvic surgeries (Brook, 2010).

Skin and soft tissue infections

Infections in the skin and soft tissue caused by anaerobic microorganisms are mainly due by contamination with the flora from adjacent mucosal surfaces, although can be also caused by cutaneous anaerobic microbiota, especially *Peptostreptococcus* (Brook, 2007). The main clinical entities in this type of infections are cutaneous abscess and wounds, diabetic foot ulcers, pressure ulcers and gas gangrene. As in other areas, infections most often are polymicrobials, yielded mixed microbiota, including aerobes and anaerobes, mainly the *B. fragilis* group and *Clostridium* spp. along with Enterobacteriaceae and *Enterococcus* spp. However, in infections caused near to oropharynx region, predominant pathogens are those present in the oral microbiota such as *Porphyromonas*, *Prevotella*, *Fusobacterium* and *Peptostreptococcus* spp. Anaerobic microorganisms can also cause deep soft tissue infections like

synergistic cellulitis, necrotizing fasciitis and gas gangrene; these infections are usually mixed infections with aerobes and anaerobes. The most important pathogens involved in deep infections are *Clostridium*, *Bacteroides*, *Peptostreptococcus* and group A β -hemolytic streptococci. A subtype of cellulitis such as Fournier gangrene may require also surgical treatment and it is characterized for affection of perineum, scrotum and the anterior abdominal wall.

Bone and joint infections

Arthritis is rarely caused by anaerobic microorganisms and most cases involve a single isolate and are secondary to hematogenous spread, trauma, or a prosthetic joint. The most frequent anaerobes encountered in this kind of infection are *B. fragilis* group, *Fusobacterium*, and *Peptostreptococcus* spp. (Brook, 2008b). In infections involving prosthetic devices, especially in shoulder joints, *Cutibacterium* could be sometimes isolated these types of samples (Levy et al., 2008).

Regarding to osteomyelitis, the predominant anaerobes in this disease are *Bacteroides* spp., while *Prevotella*, *Porphyromonas*, *Peptostreptococcus* and *Fusobacterium* are the predominant anaerobes in skull and bite infections. On the other hand, in osteomyelitis associated with wound contamination after trauma or exposure to gut microbiota, *Clostridium* spp. may be also isolated.

The main sources encountered in osteomyelitis infections are infected adjacent soft tissue areas, such as foot and decubitus ulcers, in which is frequent the isolation of aerobes and anaerobes.

Laboratory diagnostics of anaerobic infections

Samples collection and transportation

The samples should be properly collected and transported. Samples should be collected minimizing contamination by indigenous microbiota of mucosal surfaces and it is also important to remember that the samples should be taken, if it is possible, before starting antimicrobial therapy. The optimal samples are usually sterile fluids such as blood, pleural and peritoneal fluids, and also biopsy specimens. Table 4 describes the main acceptable collection procedures for the recovery of anaerobes. As it can see, in general, collection of tissues or sterile fluids is better than swab samples. The percutaneous aspiration from an abscess requires decontamination of the skin or mucosal surface. The sample should be immediately inoculated in a commercially available anaerobic-transport medium or, as alternative, to inoculate the sample in a sterile tube and cover up to the surface eliminating or minimizing the quantity of air. After the collection, a rapid transportation into the microbiology laboratory is necessary in order to preserve the anaerobes and to permit prompt microbiologic processing, because a contact with O₂ makes unviable the anaerobic microorganisms in less than 1 h.

Direct examination of the sample and gram staining

Direct macroscopic examination of the specimens for study of anaerobes may reveal several features that cause suspicion of anaerobic infection such as foul odor (due to the presence of volatile fatty acid and amine-end products of metabolism), red fluorescence due to pigmented *Prevotella* or *Porphyromonas* species, and black necrotic tissue, discharge, gas or purulence. However, the absence of these characteristics does not rule out anaerobic infection.

On the other hand, microscopic examination of the sample should include a Gram stain that may reveal the number and morphology of microorganisms and the presence of neutrophils. Because anaerobic infections are usually polymicrobial, Gram stain of exudates showing a polymicrobial microbiota could be indicative of anaerobic infections. Some anaerobes have special characteristics when they are observed by microscopy: *F. nucleatum* is a fusiform bacterium with pointed ends, *F. necrophorum* is a long "ropy" Gram-negative bacillus and *Clostridium* spp. are large "boxcar"-like Gram-positive bacillus. In some circumstances, the direct microscopic examination can lead to final diagnosis like in case of bacterial vaginosis due to the presence of "clue" cells. The presence of branching Gram-positive bacilli can mean the presence of *Actinomyces* spp., *Propionibacterium* spp. or *Bifidobacterium* spp.

Table 4 Acceptable collection procedures for anaerobic microorganism culture.

Blood collection for culture
Aspiration of sterile fluids (pleural, peritoneal, . . .)
Suprapubic puncture for urine collection
Percutaneous tracheal aspiration
Bronchoalveolar lavage
Transthoracic pulmonary puncture
Abscess percutaneous aspiration
Deep aspiration of cutaneous ulcer
Transvaginal aspiration
Biopsy samples

Sample processing: Anaerobic culture techniques

Selective and nonselective media should be used for culture of samples. As a nonselective medium, it can use the anaerobic *Brucella* blood agar (containing horse or sheep blood, additional hemin, and vitamin K₁). For the selective isolation of the *Bacteroides fragilis* group and *Bilophila*, *Bacteroides* bile-esculin agar could be used; for the selective isolation of pigmented and non-pigmented *Prevotella* and other Gram negative anaerobic rods, kanamycin-vancomycin agar with laked sheep blood to select could also be used; other media such as phenylethyl alcohol sheep blood agar may be used to inhibit facultative Gram negative rods. Finally, to inhibit swarming of several clostridia, an anaerobic broth could be inoculated. After inoculation, the media should be placed in an anaerobic atmosphere as soon as possible. The best method for this incubation is the use of an anaerobic chamber. Other methods are being also used such as boxes, plastic envelopes shorter jars and automated gas flushing devices. The only caution using jars and boxes is that they should not be opened until after 48 h of incubation to prevent premature death of anaerobes. The period of incubation in the majority of cases should be of 5–7 days.

Identification of anaerobic bacteria

Initially, a presumptive identification could be performed with antibiotic disks such as vancomycin (5 µg), colistin (10 µg), penicillin (2 U) and kanamycin (1000 µg). Table 5 shows the presumptive identification of the main anaerobic microorganisms with the use of these antibiotic disks. There have been numerous ways in which bacteria could be identified: phenotypic (physiological/biochemical characteristics), chemical analysis (MALDI-TOF, nuclear magnetic resonance (NMR) spectroscopy), and genetic and molecular analysis (including nucleic acid sequencing). Until recently, biochemical methods have been used for genus and/or species identification. However, these methods are time consuming (1–5 days of anaerobic incubation), too cumbersome and costly for many laboratories (Holdeman et al., 1977). Now, there are simple and rapid micromethod identification systems which would permit laboratories with limited facilities to identify clinically important anaerobic bacteria (e.g. API ANA BioMérieux, ANI Card, BioMérieux, MINITEK Becton-Dickinson). Application of gas liquid chromatography (GLC) for the detection of anaerobes has been the confirmation method; however, the introduction of mass spectrometry (MALDI-TOF MS) in the routine of laboratories has supposed a great revolution in the diagnosis. This technique is a useful a simple method for rapid identification of microorganisms for the routine identification of clinical isolates (Nagy et al., 2009, 2012). Recent advances in detection of anaerobic microorganisms from clinical samples include 16S rRNA gene-based methods, DNA hybridization, multiplex polymerase chain reaction, and oligonucleotide array technologies (Coltella et al., 2013). 16S rRNA aids in taxonomic placement of sequences comparing the sequences to others (Song et al., 2003).

Laboratory diagnosis of *Clostridium difficile* infection

Isolation of the bacterium from liquid or semisolid stool specimens is necessary for epidemiological investigation including typing. Diagnosis of *C. difficile* infection has been based on the detection of the microorganism by culture in CCFA (cefoxitin-cycloserine fructose agar), CCEY (cefoxitin-cycloserine egg yolk agar) or CCEYL (cefoxitin-cycloserine egg yolk agar with lysozyme) and further demonstration of the toxins. Pretreatment of the stools with a similar volume of alcohol increases the isolation rate of the bacterium. After this, direct detection of the toxins from the isolated strain by the cytotoxic assay using different cell lines is necessary. However, at this moment, the most widely method used for the diagnosis is the detection of *C. difficile* specific antigens such as glutamine dehydrogenase (GDH), and toxin A and B, by immunocromatography or ELISA techniques. A diagnostic algorithm of *C. difficile* infection is showed in Fig. 2. More recently, real-time PCR methods have been developed to detect the

Table 5 Presumptive identification with antibiotic disks of main anaerobes.

toxin B gene (*tcdB*) directly from the stool or from the strain. Molecular methods for typing (PCR-ribotyping REA, PFGE, MLST) could be used for study of outbreaks.

Treatment of anaerobic infections: Antibiotic selection

Because anaerobic infections may cause abscess formation and tissue damage, therapy for these infections usually requires the administration of effective drugs, surgical debridement and/or abscess drainage. Moreover, as many of these infections are of mixed etiology (aerobes and anaerobes), the drugs used should be active against both aerobic and anaerobic microorganisms. Most anaerobic infections are treated empirically on the basis of some features such as the result of the Gram stain, the type of infection, the microorganisms often present in these infections, and the antimicrobial resistance pattern. Antimicrobial susceptibility testing of anaerobic bacteria is performed by a minority of laboratories (Goldstein and Citron, 2011; Smith et al., 2010) due to some circumstances like that cultures usually yield a polymicrobial flora or may be falsely negative. Current recommendations emphasize the fact that antimicrobial susceptibility testing of anaerobic isolates is only needed for severe infections, to test new antimicrobial agents or to monitor local and regional resistance patterns, although a rise in the resistance of anaerobes to some drugs may indicate a greater need for this testing (Brook et al., 2013; Schuetz, 2014).

Currently, the main drugs used against the majority of anaerobic infections include metronidazole, carbapenems, β -lactam/ β -lactamase inhibitor and clindamycin. Table 6 summarizes the spectrum of activity of various antibiotics that can be used against anaerobic pathogens.

Depending on the clinical entity, a specific antimicrobial treatment should be applied due to the predominant microorganisms that may be encountered. For intraabdominal infections, antimicrobial coverage of *Bacteroides* spp. and Gram-negative aerobic microbiota is mandatory. For patients with mild-to-moderate community-acquired infections single agents such as carbapenems and β -lactam/ β -lactamase inhibitor combinations are suitable. Other valid options could be tigecycline, moxifloxacin and

Table 6 Activity spectrum of main drugs used against anaerobic microorganisms.

Antimicrobial agent	Spectrum of activity/characteristics
Penicillin, ampicillin and amoxicillin	Active against anaerobes that do not produce β -lactamase. Almost all GPACs are susceptible to them, but up to 80% of <i>B. fragilis</i> strains are resistant to penicillins. Many strains of <i>Prevotella</i> spp. and some Clostridia are also resistant.
Cephalosporins	Overall, this group has less activity in vitro than penicillin versus most anaerobes. Many strains of <i>B. fragilis</i> group, <i>Prevotella</i> , <i>Porphyromonas</i> and <i>Fusobacterium</i> species produce cephalosporinases. 85% of isolates are susceptible to cefoxitin. Cefoxitin has poor activity against Clostridia. Cefotetan is less effective than cefoxitin.
β -lactam/ β -lactamase inhibitor	Good option against β -lactamase producing anaerobes. Ceftazidime-avibactam has limited action against anaerobic microorganisms.
Metronidazole	This drug is active against Gram-negative anaerobes, including the <i>B. fragilis</i> group. Inactive versus <i>Cutibacterium</i> , <i>Actinomyces</i> and microaerophilic streptococci. Penetrates well in abscesses.
Clindamycin	This antibiotic is active against many anaerobes. Rates of resistance have increased in last years. Some Clostridia other than <i>C. perfringens</i> are resistant.
Carbapenems	All components of this group of antibiotics are equally active against anaerobes. They are resistant to most <i>Bacteroides</i> β -lactamases.
Fluoroquinolones	The most active in this class for anaerobic infections is moxifloxacin. Increased resistance in <i>B. fragilis</i> group, so no recommended for intra-abdominal sepsis
Vancomycin	Active against Gram-positive anaerobes; inactive against Gram-negative anaerobes
Macrolides	They have moderate to good in vitro activity against anaerobic microorganisms; inactive against many <i>Fusobacterium</i> spp. and some <i>B. fragilis</i> spp.
Tigecycline	Active against some anaerobes, including strains of <i>B. fragilis</i> that are resistant to β -lactams, clindamycin and fluoroquinolones

GPACs: Gram-positive anaerobic cocci.

cefoxitin. A two-drug therapy with an antibiotic active against coliforms and the other against anaerobes can be an alternative. Clindamycin is now no longer recommended for intraabdominal infections because increasing rates of resistance in *B. fragilis* group.

For oral infections, drugs active against both anaerobic microbiota of the mouth and the Gram-positive aerobic microbiota should be applied. β -lactams antibiotics (e.g. penicillins, cephalosporins) alone are not suitable because the β -lactamase production of anaerobic microorganisms. Antimicrobial treatment for these infections may include β -lactam/ β -lactamase inhibitor combinations, clindamycin or penicillin along with metronidazole.

Antimicrobial susceptibility testing

Susceptibility testing should be performed for clinically relevant anaerobic microorganisms involved in human infections. The disk diffusion method is not recommended for anaerobic pathogens, so the gradient diffusion method using Etests is the choice method (CLSI, 2012). The anaerobic strains should be sub-cultures in Brucella agar supplemented with 5% laked sheep blood, hemin, and 10 μ g/mL vitamin K1. Plates should be incubated in anaerobic atmosphere at 35–37 °C for 48 h. However, agar dilution is the gold standard in the case of MIC determination for anaerobes, although this method is not suitable for routine laboratories.

Antimicrobial resistance

Antibiotic resistance among anaerobic microorganisms has increased significantly over the past decades (Hecht, 2004; Karlowsky et al., 2012). However, resistance rates vary widely among different geographic regions. Regarding to *B. fragilis* group, resistance to penicillin may be observed in around 80–90% of isolates, while a higher proportion of the isolates (20%) are also resistant to amoxicillin-clavulanate. The overall resistance rate to carbapenems is very low (<1%), although some studies have reported higher rates (Snydman et al., 2011). The most significant changes last years in *Bacteroides* spp. have been the increase of resistance rate to clindamycin, ranging 30–50%. The most active drug against *Bacteroides* spp. is metronidazole and resistance to this antibiotic remains rare, although reports are emerging worldwide (Boyanova et al., 2015; Cobo et al., 2019).

Regarding to *Prevotella*, the resistance rate to penicillin is also increasing (Cobo et al., 2019), and their resistance rate to clindamycin is ranging 11 to 40%. Overall, *Prevotella* isolates found no resistance to metronidazole, although in some studies this resistance has been detected (Cobo et al., 2017a; Shilnikova and Dmitrieva, 2015).

On the other hand, very few isolates of *Fusobacterium* shows resistance to antibiotics, except for penicillin due to β -lactamase production.

Among *Clostridium*, *C. difficile* shows high resistance rate to imipenem (90%) and clindamycin (40%), but no resistance to metronidazole or vancomycin. Among other *Clostridium* species, resistance may be observed for all antimicrobials, except for imipenem. Non-spore-forming Gram-positive bacilli are intrinsically resistant to metronidazole, but they are highly susceptible to penicillin, β -lactams/ β -lactamase inhibitor, and carbapenems. The rate of resistance to clindamycin is highest for *Actinomyces* and lowest for *Cutibacterium*.

Finally, regarding to GPACs no resistance to carbapenems and β -lactams/ β -lactamase inhibitor may be observed in any genera. On the other hand, resistance to moxifloxacin is high in all genera, ranging between 25% and 46%. In this group of microorganisms,

the resistance rate to clindamycin is much higher for *Finegoldia* (around 50%) and *Peptoniphilus* (around 40%). Some GPAC strains have shown resistance to metronidazole (Cobo et al., 2017b).

In conclusion, routine antimicrobial susceptibility testing for anaerobes contributes information on the global situation and permits empirical therapies to be selected in accordance with local data on resistant strains.

General characteristics

The *Enterobacterial* family contains numerous and varied species, being the largest and most varied group of gram-negative bacilli of clinical importance. These have characteristics in common and are classified according to their biochemical properties, structural antigens, molecular analysis of the genome through sequencing and by analyzing the composition of their proteins using mass spectrometry (Murray et al., 2014).

They are ubiquitous microorganisms, we can find them in soil, water and vegetation, and the most important thing is that as a common niche they are part of the intestinal microbiota of animals, including humans. They produce a great variety of infections in humans, about one third of all bacteremias, more than 70% of urinary tract infections (UTI), as well as many abdominal infections (Eliason, 1940).

Depending on the clinical infections they produce, members of the *Enterobacterales* family can be divided into two broad categories: opportunistic pathogens and primary pathogens.

Primary pathogens (*Yersinia pestis*, *Salmonella* serotype Typhi, *Shigella*) cause disease whenever they are detected in clinical samples; while those that are part of the commensal microbiota (*Escherichia coli*, *Klebsiella pneumoniae*, *Proteus* sp., . . .) can produce opportunistic infections.

Physiology and structure

They are all gram-negative, intermediate-sized ($0.3\text{--}1.0 \times 1.0\text{--}6\text{ }\mu\text{m}$), non-spore-forming, facultative anaerobes. They can grow on general media (e.g., blood agar) or on selective media (e.g., MacConkey agar). As nutritional requirements they are undemanding, glucose fermenting, nitrate reducing, catalase positive and oxidase negative.

Selective and differential media allow us a presumptive identification since these media contain one or more carbohydrates (lactose, sucrose) that can be fermented by some of these bacteria. This change is visible thanks to a color change in the medium, caused by a decrease in pH detected by a pH indicator incorporated in the medium (Eliason, 1940).

Lactose fermentation allows us to differentiate fermenting strains (*Escherichia*, *Klebsiella*, *Enterobacter*, *Citrobacter* and *Serratia*; pink colonies on MacConkey agar) from non-fermenting or slow fermenting strains (*Proteus*, *Salmonella* and *Yersinia* species; colorless colonies on MacConkey agar). There are other media in which resistance to bile salts allows us to differentiate enteric pathogens (*Salmonella*, *Shigella*) from commensals that are inhibited by bile salts.

Virulence and antigenic factors

The ability to adhere, colonize, produce toxins and invade tissues are some of the many factors that affect the virulence of enterobacteria. Some species harbor plasmids through which resistance gene transfer can occur (Eliason, 1940).

Regarding the antigenic structure of the cell wall, lipopolysaccharide (LPS) is the main antigen of the wall, consisting of three components.

- Polysaccharide O or somatic, the most external. Important for epidemiological classification within a species.
- A central polysaccharide, shared by all enterobacteria, is used to classify a microorganism as a member of the *Enterobacterales* family.
- Lipid A, responsible for endotoxin activity (important virulence factor).

The classification into serological groups is based on three groups of antigens. These antigens include the following:

- antigen or somatic antigen: it is a thermostable antigen located in the cell wall, present in every genus and species.
- H antigen or flagellar antigen: it is a thermolabile antigen found on the surface of flagella, structures responsible for motility.
- K antigen or capsular antigen: a thermolabile polysaccharide found only in some encapsulated species (K1 antigen of *Escherichia coli* and Vi antigen of *Salmonella enterica* subsp. *enterica* serotype Typhi).

The detection of these antigens has not only epidemiological but also clinical relevance. Some species are associated with specific O and H serotypes, such as *E. coli* O157:H7 associated with hemorrhagic colitis.

As for virulence factors, there are some common to all genera, while others are specific to virulent strains.

Endotoxin

It is a virulence factor shared by aerobic and some anaerobic gram-negative bacteria. Its activity depends on lipid A, released during cell lysis.

Capsule

It serves as protection during phagocytosis by hydrophilic capsular antigens, which interfere with the binding of antibodies to bacteria and are poorly immunogenic or complement activators.

Antigenic phase variation

Somatic O antigens, capsular K antigens and flagellar H antigens can be alternatively expressed or not expressed (phase variation), thus providing protection against antibody-mediated cell destruction.

Type III secretion systems

This is an effector system for transferring their virulence factors to target eukaryotic cells. In the absence of this system, bacteria are less virulent.

Opportunistic members of the family Enterobacteriaceae and associated infections

Escherichia coli

E. coli is the most frequent and important member of the genus. It is associated with multiple diseases, including gastroenteritis, urinary tract infections (UTI), meningitis and sepsis (Croxen and Finlay, 2010).

Most strains of *E. coli* are motile and generally possess adhesive fimbriae, sexual pili and O, H and K antigens. The O groups of *E. coli* have shown remarkable cross-reactivity with the O antigens of other members of the Enterobacteriaceae, particularly *Shigella* spp. (Eliason, 1940).

Pathogenesis

E. coli, in addition to possessing the general virulence factors of the Enterobacteriaceae family, possesses a wide variety of specialized virulence factors such as adhesins and exotoxins.

Adhesion to the host cells occurs in all *E. coli* cells with the exception of ECEI (enteroinvasive *E. coli*), and is often achieved by means of the fimbriae or pili. Following adhesion, *E. coli* counteract host cell mechanisms using secreted proteins. Hijacking and manipulation of host cell signaling pathways can result in coordinated invasion of host cells, evasion of host immune responses, and efficient colonization, ultimately leading to disease (Croxen and Finlay, 2010).

Epidemiology

E. coli resides in large numbers in the gastrointestinal tract, but can behave as an opportunistic pathogen. Most diseases are therefore endogenous, due to an alteration in the patient's defenses (e.g., through trauma or suppression of immunity) they gain access to the peritoneal cavity and can cause extraintestinal or digestive symptoms, with the exception of meningitis and neonatal gastroenteritis.

Most *E. coli* cause disease by acquiring virulence factors encoded in plasmids or bacteriophage DNA (Kolenda et al., 2015).

Clinical manifestations

Gastrointestinal

E. coli can cause several different gastrointestinal syndromes. According to virulence factors, clinical manifestations, epidemiology and the different O and H serotypes, there are five main categories.

(a) Enterotoxigenic *E. coli* (ECET)

It is associated with diarrhea in adults and especially children in tropical and subtropical climates in developing countries, where it is a major cause of bacterial diarrhea in children. In developed countries it is the most common cause of diarrheal disease, sometimes referred to as "traveler's diarrhea". TCD infection is acquired primarily through consumption of contaminated food or water. Poor hygienic hygiene, poor availability of drinking water sources and inadequate sanitation are the main factors contributing to the transmission of this disease. A high infectious dose (10^6 – 10^{10} microorganisms) is needed to initiate disease in an immunocompetent host (Murray et al., 2014).

Watery diarrhea occurs after an incubation period of 1–2 days and lasts 3–5 days. Symptoms are non-bloody watery diarrhea with abdominal cramping, less frequently nausea and vomiting.

It is known that colonization of ECET in the proximal small intestine is mediated by fimbriae or surface proteins (colonization factors (CF)), which allow ECETs to bind to specific receptors on intestinal microvilli. These CFs are encoded in a transmissible plasmid. Once attached, they can release one and/or two types of toxins:

- Thermostable toxin (STa and STb)
- Thermolabile toxin (LT-I, LT-II)

STa toxin is detected in 75–80% of TSEs, alone or in association with LT, and is responsible for the majority of severe cases. It is a monomeric peptide that binds to the guanylate cyclase receptor, causing an increase in cyclic guanosine monophosphate concentrations and thus hypersecretion of fluids and inhibition of fluid absorption (Isidean et al., 2011).

As for LT, LT-II is not associated with disease in humans, whereas LT-I is functionally and structurally similar to cholera toxin. LT consists of two fragments (A and B), where A is the enzymatically active portion. The B, or binding, portion confers specificity. The B portion binds to the GM1 ganglioside of the intestinal mucosa, allowing entry of the A portion. During infection, the A portion activates cellular adenylate cyclase, leading to increased conversion of adenosine triphosphate to cyclic adenosine monophosphate (cAMP). The consequence of cAMP accumulation is hypersecretion of electrolytes and fluids into the intestinal lumen, resulting in cholera-like watery diarrhea (Croxen and Finlay, 2010).

(b) Enteropathogenic *E. coli* (ECEP)

Although the EPEC strain has been known to cause childhood diarrhea since the 1940s, its pathogenic role has remained controversial in recent decades.

The disease is sporadic and outbreaks are infrequent in developed countries; currently cases occur in impoverished countries and mainly affect infants. Transmission is fecal-oral through contaminated surfaces or food (Croxen and Finlay, 2010).

The disease is characterized by watery diarrhea, with low-grade fever, malaise, and vomiting. The stool usually contains large amounts of mucus, but no blood is apparent. Onset may be rapid, and although it usually resolves within a few days, persistent diarrhea may occur, necessitating hospitalization.

(c) Enteraggregative *E. coli* (ECEA)

It is a heterogeneous group of strains characterized by producing diarrhea by adhering to the epithelium of the intestinal mucosa forming a stacking pattern in "brick piles."

It causes watery diarrhea, vomiting, dehydration and occasionally abdominal pain, especially in children. It is one of the few bacteria associated with chronic diarrhea and growth retardation in children. Symptoms usually persist for at least 2 or more weeks.

(d) Shiga toxin-producing *E. coli* or Enterohemorrhagic *E. coli* (EHEC)

Members of this group are defined by the presence of Shiga toxin 1 (Stx1) or 2 (Stx), with serotype O157:H7 being the most frequent.

Stx-1 is a cytotoxin identical to the Shiga toxin produced by *Shigella dysenteriae*, while Stx-2 has 60% homology, both encoded from lysogenic bacteriophages.

Transmission of the disease most often occurs through consumption of undercooked beef or other meat products, water, unpasteurized milk or raw fruit and vegetable juices such as spinach. A small ingestion of bacteria is needed to cause disease, and person-to-person transmission has also been described.

The classic disease caused by ECEH produces a watery diarrhea progressing to bloody diarrhea with abdominal cramping and low fever or absence of fever. The stool does not contain leukocytes, which distinguishes it from dysentery caused by *Shigella* spp. or ECEI infections. The infection is life-threatening and is usually associated with serotype O157:H7.

Hemolytic uremic syndrome (HUS), a disorder characterized by acute renal failure, thrombocytopenia, and hemolytic-microangiopathic anemia, is a complication affecting 5–10% of children under 10 years of age. It usually resolves within 4–10 days in uncomplicated cases, but 3–5% of patients may die or severe sequelae may appear (Amézquita-López et al., 2018).

(e) Enteroinvasive *E. coli* (ECEI)

ECEI strains are rare in both developed and developing countries.

Enteroinvasive strains produce dysentery with direct penetration, invasion and destruction of the intestinal mucosa.

Direct transmission is from person to person by the fecal-oral route. Clinical infection is characterized by fever, severe abdominal cramps, malaise and watery diarrhea.

Although ECEI and *Shigella* spp. are morphologically similar, ECEI and *Shigella* spp. produce similar clinical disorders, the infectious dose of ECEI necessary to produce the disease is much greater (10^6) than that of shigellae (about 100 bacterial cells) (Croxen and Finlay, 2010).

Extraintestinal infections

(a) Urinary tract infection

Urinary tract infections caused by gram-negative bacilli occur mostly by ascension from the colon through the urethra to the bladder, and may reach the kidneys or prostate. In most of the cases the pictures are produced by more virulent strains, with capacity to produce adhesins and hemolysins (Bennet et al., 2016).

(b) Neonatal meningitis and septicemia

E. coli is a major cause of septicemia and meningitis in neonates, accounting for about 40% of gram-negative meningitis.

The K1 capsular antigen present in certain strains of *E. coli* is the virulence factor that is associated with neonatal meningitis infections, it is immunochemically identical to the capsular antigen of *N. meningitidis* group B. (Eliason, 1940).

Klebsiella

Members of this genus are commonly found as part of the intestinal tract of humans and animals.

These microorganisms are associated with various opportunistic infections both at the nosocomial and community level (especially pneumonia, wound infections and urinary tract infections) (Murray et al., 2014).

The genus *Klebsiella* consists of several species, among which are *Klebsiella pneumoniae* subsp. *pneumoniae*, *K. oxytoca*, *K. pneumoniae* subsp. *ozaenae*, *K. rhinoscleromatis* and *K. ornithinolytica*. All species possess a capsule that confers the mucoid appearance to the isolated colonies, in addition to protection against phagocytosis and absorption of antimicrobials (Eliason, 1940).

The most common species of pneumonia are *K. pneumoniae* and *K. oxytoca*, which can produce lobar pneumonia. This type of pneumonia generally produces necrotic destruction of the alveolar spaces, cavity formation and the production of hemoptotic sputum. In addition to this type of infections we can also find them as producers of skin and soft tissue infections and UTIs.

In the case of *Klebsiella granulomatis* it is the etiological agent of granuloma inguinale or Donovanosis, a granulomatous disease affecting the genitals and groin area. It can be transmitted through sexual intercourse or genital trauma. After an incubation period of weeks to months, subcutaneous nodules appear on the genitals or in the inguinal region. These granules rupture giving rise to painless lesions which may resemble syphilitic lesions.

Klebsiella pneumoniae subsp. *rhinoscleromatis* has been isolated from patients with rhinoscleroma, an infection of the nasal cavity that manifests as intense swelling and malformation of the entire face and neck (Murray et al., 2014).

Enterobacter, Citrobacter and Serratia

Genus *Enterobacter*

The genus *Enterobacter* is composed of at least 12 species, among which *Enterobacter cloacae*, *Enterobacter aerogenes*, *Enterobacter gergoviae* and *Enterobacter hormaechei* are most frequently isolated from clinical specimens. Members of this genus are motile. The macroscopic appearance of colonies in many cases resembles *Klebsiella* when grown on MacConkey agar. *E. cloacae* and *E. aerogenes* are the two most common isolates of this group and have been isolated from wound, urine, blood and CSF samples.

E. gergoviae is found in respiratory samples and is rarely isolated in blood cultures. *Enterobacter sakazakii* has been isolated as a pathogen in bacteremia, meningitis, respiratory and wound infections (Mezzatesta et al., 2012).

Genus *Citrobacter*

The genus *Citrobacter* consists of at least 11 species that have been isolated from clinical specimens. Most *Citrobacter* spp. slowly hydrolyze urea and ferment lactose, producing colonies on MAC agar that resemble those of *E. coli*.

Bacteria of this genus are commensals of the gastrointestinal tract and are associated with hospital-acquired infections, most frequently UTI. The three most frequently isolated species are *C. freundii*, *C. koseri* and *C. braakii*.

C. freundii mainly causes nosocomial infections (urinary tract infections, pneumonias and intra-abdominal abscesses).

C. amalonaticus is frequently found in feces, but has not been described as a causative agent of diarrhea, it has been isolated as a producer of extraintestinal infections (Lipsky et al., 1980).

Genus *Serratia*

The genus *Serratia* includes *S. marcescens*, *S. liquefaciens*, *S. rubidaea*, *S. odorifera*, *S. plymuthica*, *S. ficaria*, *S. entomophila*, and *S. fonticola*.

Serratia spp. is an opportunistic pathogen associated with outbreaks in healthcare settings. *Serratia* spp. are also known to be resistant to a wide range of antimicrobials.

S. marcescens, *S. rubidaea* and *S. plymuthica* usually produce a characteristic pink to red pigment, prodigiosin, especially when cultures are incubated at room temperature. The pigment is a typical characteristic of strains of environmental origin.

S. marcescens is the species considered most clinically important. It has been frequently encountered in hospital urinary or respiratory tract infections and in respiratory outbreaks and bacteremic outbreaks in day care centers and cardiac surgery and burn units.

S. odorifera contains two biogroups. *S. odorifera* biogroup 1 is predominantly isolated from the respiratory tract, *S. odorifera* biogroup 2 has been isolated from blood and CSF (Murray et al., 2014).

Proteus, Morganella and Providencia

The genera *Proteus*, *Morganella* and *Providencia* belong to the tribe *Proteeae*. They are widely distributed in the environment and are part of the normal intestinal microbiota.

Genus *Proteus*

This genus consists of five species, *P. mirabilis*, *P. vulgaris*, *P. penneri*, *P. myxofaciens* and *P. hauseri* (O'Hara et al., 2000).

P. mirabilis and *P. vulgaris* are widely recognized human pathogens. Both species have been isolated from urine specimens, wounds and ear infections (Eliason, 1940).

P. mirabilis is the most frequent member of this genus, producing mainly urinary tract infections. This microorganism produces large amounts of urease, cleaving urea into carbon dioxide and ammonium. This causes an increase in urinary pH, and therefore the precipitation of magnesium and calcium in the form of struvite and apatite crystals, which results in the formation of kidney stones. In addition this increase in pH is also toxic to the urothelium (Murray et al., 2014).

Genus *Morganella*

The genus *Morganella* contains a single species, *M. morganii*, with two subspecies: *M. morganii* subsp. *morganii* and *M. morganii* subsp. *sibonii*. Neither *M. morganii* subsp. *M. morganii* is a documented cause of UTI. It has also been identified as a cause of neonatal sepsis. *Morganella* is motile but does not swarm (Eliason, 1940).

M. morganii is widely distributed in nature, commonly found in the environment and in the intestinal tract of humans, mammals and reptiles as part of the normal flora. Drug resistance of *M. morganii* is increasing in recent years, and this resistance is introduced mainly through extra-genetic and mobile elements. Infections caused by multidrug-resistant (MDR) or even extensively drug-resistant (XDR) *M. morganii* often result in clinical treatment failure. In general, *M. morganii* can produce virulence factors, such as urease, hemolysins, and lipopolysaccharide (LPS); these virulence factors make *M. morganii* an opportunistic pathogen that mainly causes wound and urinary tract infections (Liu et al., 2016).

Genus *Providencia*

The genus *Providencia* consists of five species: *P. alcalifaciens*, *P. stuartii*, *P. rettgeri*, *P. rustigianii* and *P. heimbachae* (Shah et al., 2019).

P. rettgeri is a documented pathogen of the urinary tract and has caused occasionally outbreaks in healthcare settings. Similarly, *P. stuartii* has been implicated in outbreaks in burn units and has been isolated in urine cultures. Infections caused by *P. stuartii* and *P. rettgeri*, especially in immunocompromised patients, are particularly difficult to treat because of their antimicrobial resistance.

P. alcalifaciens is most frequently found in the feces of children with diarrhea; however, its role as a cause of diarrhea has not been demonstrated.

P. rustigianii, previously identified as a strain of *P. alcalifaciens*, is rarely isolated, while *P. heimbachae* has not yet been isolated from any clinical specimens (Eliason, 1940).

P. rettgeri and *P. stuartii* are generally resistant to gentamicin and tobramycin, but susceptible to amikacin. Urine isolates are susceptible to oral extended-spectrum cephalosporins, ciprofloxacin, and amoxicillin-clavulanate. *Providencia* spp. are also susceptible to ceftazidime, cefotaxime. Alternative options for antimicrobial therapy include ceftriaxone, imipenem, and trimethoprim-sulfamethoxazole (O'Hara et al., 2000).

Primary intestinal pathogens of the family Enterobacteriaceae

Salmonella, *Shigella* and *Yersinia* are microorganisms that cause gastrointestinal disease in humans, they are not part of the normal microbiota of the human gastrointestinal tract.

Humans acquire the infection by ingesting the microorganisms through food products of animal origin, poultry, milk, and undercooked dairy products. Some *Salmonella* infections can be transmitted through human carriers.

Infections caused by *Shigella* spp. are associated with human carriers responsible for the spread of the disease; an animal reservoir has not yet been identified. *Shigella* dysentery usually indicates inadequate sanitary conditions and poor personal hygiene. *Yersinia* spp. infections are transmitted by a wide variety of wild and domestic animals. *Yersinia* infections include gastrointestinal disease, mediastinal lymphadenitis, fulminant septicemia and pneumonia (Eliason, 1940).

Salmonella

Members of the genus *Salmonella* cause important infections in humans and certain animals. Many *Salmonella* serotypes are typically found in cold-blooded animals, as well as in rodents and birds, which are their natural hosts.

Salmonella spp. are gram-negative, facultative anaerobic bacilli that morphologically resemble other enteric bacteria. On selective and differential media used primarily to isolate enteric pathogens, *Salmonella* spp. (e.g., MAC), grow as clear, colorless colonies without lactose fermentation. On media with indicators for H₂S production (Hektoen or XLD), colonies with centers are observed (Eliason, 1940).

Most of the isolates of clinical significance belong to the *Salmonella enterica* species. Within the species *S. enterica* there are six subspecies (subspecies VI).

Pathogenesis

Once ingestion occurs and they reach the stomach, they bind to the small intestinal mucosa and invade M cells (microfolds), which are located in Peyer's patches and enterocytes. Bacteria can: replicate within endocytic vacuoles and transport through the cytoplasm to be released into the blood or lymphatic circulation.

The processes of regulation of anchoring, engulfment and replication are due to two aggregates of genes, called pathogenicity islets I and II.

Epidemiology

Salmonella is able to colonize multiple animals (poultry, reptiles, cattle, rodents, domestic animals. . .). The spread from one animal to another and the use of feed contaminated with *Salmonella* maintain an animal reservoir. In the case of *Salmonella* Typhi and Paratyphi, the reservoir is only human and therefore only produce disease in humans.

In most cases, infection occurs by ingestion of contaminated products (poultry, eggs, dairy products or products prepared on contaminated surfaces) or by the fecal-oral route. The incidence is higher in children under 5 years of age and adults over 60 years of age. It is estimated that there are about 1.2 million infections and 400 deaths per year (Murray et al., 2014).

In the case of *Salmonella* Typhi infections, the infection is contracted through contaminated food and water by an infected handler. An estimated 27 million infections and 200,000 deaths occur from *Salmonella* Typhi and Paratyphi (ECDC, 2018).

Clinical manifestations

There are different pictures of *Salmonella* infection:

- Gastroenteritis
- Typhoid fever, the most severe form being enteric fever.
- Septicemia
- Asymptomatic colonization

It is the most common form of food poisoning, produced by the ingestion of contaminated food. *Salmonella* strains associated with gastroenteritis are usually strains found in animals, most of these strains are members of *S. enterica* subsp. *enterica* (Eliason, 1940).

Symptoms usually appear between 6 and 48 h after ingestion of contaminated food or water, with nausea, vomiting and non-bloody diarrhea. Fever, abdominal spasms, myalgia and headache are also common. Most cases of *Salmonella* gastroenteritis are self-limiting, with symptoms persisting for 2–7 days (Murray et al., 2014).

Antimicrobial therapy is not usually indicated in uncomplicated cases. Antimicrobial therapy is believed to prolong the carrier state (Eliason, 1940).

- Typhoid fever

Enteric fever caused by *Salmonella* Typhi is known as typhoid fever, a febrile illness resulting from ingestion of food contaminated with the organisms from infected individuals or carriers. Clinical features of enteric fevers include:

- Prolonged fever
- Bacteremia
- Reticuloendothelial system involvement.

A mild form of the disease is produced by *Salmonella* Paratyphi A, *Salmonella* Schottmuelleri and *Salmonella* Hirschfeldii (Murray et al., 2014).

Typhoid fever develops around 9–14 days after ingestion of the bacilli, beginning with a progressively increasing fever and nonspecific symptoms such as headache, myalgia, malaise and myalgias. These symptoms last about 1 week, and are followed by gastrointestinal symptoms. This cycle corresponds to an initial bacteremic phase which is followed by colonization of the gallbladder and subsequent reinfection of the intestine.

- Septicemia

Prolonged fever and intermittent bacteremia, identical to that of other gram-negative bacilli, occurs. The serotypes most commonly associated with bacteremia are *S. Typhi*, *Paratyphi* and *Choleraesuis*.

The highest risk of developing *Salmonella* bacteremia is in pediatric, geriatric and immunocompromised patients.

- Asymptomatic colonization

Chronic colonization for more than 1 year after symptomatic infection occurs in 1–5% of patients, mainly by *Salmonella* species responsible for typhoid fevers, the reservoir in most cases being the gallbladder. In the case of infections by other *Salmonella* species, chronic colonization occurs in less than 1% (Murray et al., 2014).

Shigella

Four species have been described from almost 50 serogroups based on the O antigen: *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii* and *Shigella sonnei*. It is known from DNA molecular studies that *Shigella* and *Escherichia* are closely related, and therefore these 4 species constitute a biogroup within the *E. coli* species. However, they are kept distinct so as not to lead to confusion (Murray et al., 2014).

Pathogenesis

The disease occurs when *Shigella* invades the cells of the colon where they replicate. The genes that regulate the process of adherence, replication, invasion and dissemination are located on a virulence plasmid that is regulated by a chromosomal gene (Murray et al., 2014).

Shigella binds to M cells, once attached and by means of a type III secretion system are phagocytosed. They then lyse the vacuole and replicate in the cytoplasm. These bacteria are known to survive phagocytosis as they induce a process of apoptosis (Kotloff et al., 2018).

In the case of *S. dysenteriae* it produces an exotoxin, Shiga toxin. It contains one A and five B subunits. The B subunits facilitate the passage of the A subunit into the cell, the A subunit separates the 28S rRNA from the 60S unit, alternating protein synthesis. It mainly causes damage to the intestinal epithelium but can also cause damage to glomerular endothelial cells (Niyogi, 2005).

Epidemiology

Humans are the only reservoir for *Shigella*. About 90 million cases occur annually, with *S. sonnei* being the main culprit in developed countries, while in developing countries *S. flexneri* is predominant. In addition, epidemics of *S. dysenteriae* occur with mortalities of 5–15% (Niyogi, 2005).

Shigellosis affects mainly pediatric ages, reaching 60% in children under 10 years of age (ECDC, 2020).

Shigellosis is transmitted from person to person by the fecal-oral route, primarily from people with contaminated hands (Murray et al., 2014).

Clinical manifestations

The clinical manifestations of shigellosis vary from asymptomatic to severe forms of the disease. The main symptoms are high fever, chills, abdominal spasms, diarrhea and bloody stools, appearing between 24 and 72 h after ingestion of the bacteria.

The organisms, which originally multiply in the small intestine, move to the colon, where they can be isolated 1–3 days after infection develops (Eliason, 1940).

The main feature of shigellosis is abdominal spasms and tenesmus with abundant pus and blood in the stool, this is due to the invasion of the colonic mucosa by the bacteria.

Resolution of the disease is usually spontaneous, although antimicrobial treatment is recommended to reduce the course of disease (Niyogi, 2005).

Yersinia

The genus *Yersinia* consists of 14 species, most of which are considered environmental species.

Only three species are considered pathogenic in humans: *Y. pestis* (causative agent of plague), *Y. pseudotuberculosis* and *Y. enterocolitica* (enteric pathogens).

Pathogenesis

Yersinia species are able to resist phagocytosis by dephosphorylating proteins necessary for phagocytosis (*YopH* gene), inducing cytotoxicity by alternating actin filaments (*YopE* gene) and inducing apoptosis in macrophages (*YopJ/P* gene).

As for *Yersinia pestis* it possesses two additional plasmids, the fraction 1 (*f1*) gene encoding an antiphagocytic protein capsule and the plasminogen activator protease (*pla*) gene, which prevents opsonization and phagocytic migration by degrading complement components (Iriarte and Cornelis, 1996).

Epidemiology

Yersinia infections are all zoonotic, with humans acting as accidental hosts.

In the case of *Yersinia pestis* infection, two forms can be distinguished:

- Urban plague (rats as reservoir)
- Wild plague (squirrels, rabbits, wild rats as reservoir)

In *Yersinia enterocolitica* infections the reservoir are pigs, rodents, cattle and rabbits; in *Yersinia pseudotuberculosis* infections the reservoir are rodents, wild animals and game birds (Black and Slome, 1988).

Plague has been one of the most devastating diseases in history, causing up to three epidemics. Currently, around 10 cases per year are described, mostly of the wild type.

In urban plague, the reservoir is rats and transmission to humans occurs through the bite of the rat flea, which has been eliminated in most communities by controlling rat populations and improving hygiene. In the case of feral plague, it is very difficult to control due to the universal distribution of reservoirs (Fàbrega and Vila, 2012).

Y. enterocolitica is a frequent cause of enterocolitis in northern Europe and North America. Ninety percent of infections are due to consumption of contaminated meat, milk or water. The virulence of infection is associated with certain serotypes, such as O3 and O9.

Clinical manifestations

- Bubonic plague (*Y. pestis*)

Following the bite of an infected flea, symptoms begin within 7 days. The picture presents with high fever and a painful bubo (inflammatory lymphadenopathy) in the groin or axilla area. Bacteremia develops rapidly and up to 75% die.

- Pneumonic plague (*Y. pestis*)

In this case the incubation period is shorter (2–3 days), they present fever and general malaise with pulmonary symptoms appearing on the first day. The mortality rate in untreated cases can reach 90%.

- Enterocolitis (*Y. enterocolitica*)

The incubation period is between 1 and 10 days, the symptoms that develop are diarrhea, fever and abdominal pain. The disease affects the terminal ileum and acute appendicitis may develop.

Laboratory diagnosis of enterobacterales

Isolation and identification

Enterobacteriaceae grow easily in culture media, they are facultative anaerobes and grow at an optimum temperature between 35 °C and 37 °C.

Some species (*Serratia*, *Yersinia*) can grow at low temperatures (1–5 °C).

On non-selective and differential media they grow after 18–24 h of incubation.

Cultivation

Most laboratories use a variety of non-selective media, such as blood agar and chocolate agar, as well as selective media, such as MacConkey, especially for samples where polymicrobial flora may be growing.

On chocolate agar or blood agar plates, enteric bacteria produce large, grayish, smooth colonies. On blood agar, colonies may be β -hemolytic or nonhemolytic. Differential media allow separation of lactose-fermenting enterobacteria (pink color) from non-fermenting enterobacteria (transparent color). In the case of the diagnosis of ECTS O157:H7 (non-sorbitol-fermenting), sorbitol MacConkey agar is used, allowing differentiation of these colonies because they are colorless colonies in this medium. Subsequently, it is confirmed by serogroup tests. Unfortunately there are strains that ferment sorbitol, therefore the preferred diagnosis is the detection of Shiga toxin by immunoassay or molecular methods.

To recover microorganisms such as *Salmonella* or *Shigella*, there are media such as Hektoen agar, XLD or SS in which H_2S production can be appreciated (Eliason, 1940).

Biochemical identification

Currently most laboratories use different automated systems that allow the identification of virtually all family members within 24 h. In addition, the sequencing of species-specific genes such as the 16S rRNA gene or the detection of protein profiles using mass spectrophotometry can be performed.

Treatment

Treatment of enterobacterial infections should be based on in vitro sensitivity testing and clinical experience. Certain enterobacteria such as *E. coli* and *P. mirabilis* are usually sensitive to many antibiotics, but there may be production of enzymes that inactivate penicillins and cephalosporins, such as extended spectrum beta-lactamases (EBLECs) or enzymes that inactivate carbapenemics. BLEEs are usually quite widespread in *E. coli* and *K. pneumoniae* (Cercenado, 2015).

Antibiotic resistance is more frequent in nosocomial infections than in community infections, and multidrug-resistant profiles may appear more and more frequently, complicating the treatment of infections.

There are also certain infections where antibiotic treatment is not recommended if not symptomatic treatment, as in the case of gastroenteritis caused by Shiga toxin-producing *E. coli* or *Salmonella*, as they can prolong the carrier state or increase the risk of secondary complications (Gut et al., 2018).

Microbiology

The genus *Vibrio* belongs to the family *Vibrionaceae*, is composed of Gram-negative curved rods 0.5–0.8 µm wide and 1.4–2.6 µm long, and mobile. They are part of natural aquatic habitats, preferably warm and saline waters. Most species of this genus are halophilic and need NaCl requirements in culture media for growth, although *V. cholerae* and *Vibrio mimicus* can grow in most common culture media without this requirement. They tolerate a wide pH range (6.5–9) well, but are sensitive to acidic pH, which is why people with reduced gastric acid are more susceptible to *Vibrio* infections.

In its structure we can find the presence of a polar flagellum, responsible for motility, and pili on the surface, which are involved in the virulence of the different species. The cell wall has lipopolysaccharides formed by Lipid A (endotoxin), central polysaccharide and polysaccharide O, the latter is used to classify *Vibrio* species by serogroups.

There are about 30 species of *Vibrio*, but only 12 have been recognized as pathogenic to humans, including: *V. cholerae*, *V. parahaemolyticus*, *V. vulnificus*, *V. alginolyticus*, *V. mimicus*, *V. fluvialis*, *V. cincinnatiensis*, *V. hollisae*, *V. furnissii*, *V. damsela*, *V. metshnikovii* and *V. carchariae* (Baker-Austin et al., 2018).

All these pathogenic *Vibrios* are responsible for foodborne diseases, but the most important ones are considered to be *V. cholerae* O1 and O139, *V. parahaemolyticus* and *V. vulnificus* because of the serious clinical manifestations they can cause (Fig. 1).

Phenotypically these species are oxidase and catalase positive, able to ferment glucose without gas production.

V. parahaemolyticus and *V. vulnificus* are phenotypically similar, but can be differentiated biochemically because *V. vulnificus* ferments lactose and β-D-galactosidase sugars unlike *V. parahaemolyticus*.

In the case of *V. cholerae* can differentiate more than 200 serogroups, which includes pathogenic and nonpathogenic species, so *V. cholerae* O1 and *V. cholerae* O139 are cable of synthesizing the cholera toxin and be responsible for the clinical manifestation called cholera, these serogroups are differentiated by the presence or absence of methylated O antigen. The remaining species are referred to as *V. cholerae* non-O1, non-O139. *V. cholerae* O1 is further subdivided into serotypes and biotypes. The biotypes are called Classical and El Tor, which differ in phenotypic traits, such as biochemical tests and different susceptibility to bacteriophages. Both can be serotypes Inaba, Ogawa and Hikojima, which express different antigens, the latter being a transitional state that expresses antigens of the previous two (Fig. 2). The Inaba and Ogawa serotypes differ in the absence or presence, respectively, of a methyl group on the terminal sugar of the O antigen (Harris et al., 2012).

V. cholerae O139, arose after the acquisition of a genomic island containing the *rfb* region, which includes the genes required for the synthesis of the O139 antigen.

The prevalence of one serotype or another has changed over time and they have been responsible for the different pandemics, such that classical *V. cholerae* O1 is attributed to the fifth and sixth pandemics (and possibly the previous ones) and the seventh to the El Tor biotype (Lekshmi et al., 2018).

These bacteria have in their genomic structure two circular chromosomes, formed by genetic recombination and horizontal gene transfer, we can also find the presence of plasmids responsible for antimicrobial resistance.

For *V. cholerae*, on circular chromosome 1, we find most genes responsible for DNA replication, translation and transcription, while on chromosome 2, we find genes responsible for pathogenicity, such as those encoding choleric toxin, toxin co-regulated pilus and chemotactic agents (Baker-Austin et al., 2018).

V. parahaemolyticus is also differentiated into different serogroups based on somatic O antigen and capsular K antigen, recognizing a total of 76 serotypes (González-Escalona et al., 2008).

Fig. 1 Classification pathogenic *Vibrios*.

Fig. 2 Classification *V. cholerae* O1.

Pathogenesis and immunity

The mechanism of transmission of cholera, both *V. cholerae* O1 and O139, is the fecal-oral route, and both have the same mechanism of pathogenicity. After ingestion of *V. cholerae*, either by consumption of water or food contaminated with this water, it reaches the intestine where the cholera toxin will perform its action and is the main virulence factor responsible for the characteristic diarrheal symptoms of cholera.

The infectious process begins when the person ingests water or food contaminated with *V. cholerae*, a high infective dose is required, at least an inoculum of $10^6 - 10^8$, this reaches the cells of the digestive mucosa and secretes the cholera toxin, without the destruction of these cells.

The choleric toxin is an exotoxin formed by the A-B complex, the A fraction is bound by non-covalent bonds to the B subunit of a pentameric complex, which binds to the GM1 ganglioside receptors of intestinal epithelial cells, The A fraction is then internalized and interacts with G proteins, which activate the enzyme adenylate cyclase, which catalyzes the catabolic reaction of ATP to cAMP, thereby increasing the intracellular cAMP concentration. This increase in cAMP leads to hypersecretion of water and electrolytes such as chloride ion through apical channels of transmembrane conductance (CFTR) and bicarbonate and decreased sodium reabsorption, all leading to a large loss of fluid with high ion concentrations (Yoon and Waters, 2019; Weil and Ryan, 2018).

The choleric toxin is encoded by a filamentous bacteriophage (CTXφ) and consists of two subunits, ctxA and ctxB. The bacteriophage binds to the toxin co-regulated pilus (TCP) and inserts its genetic material into the genome of the host bacterium. This TCP in turn is encoded within a genomic pathogenicity island called the *Vibrio* pathogenicity island (VPI).

In addition to the action of the toxin itself, there are other factors that contribute to virulence, such as the toxin co-regulated pilus gene complex (TCP) and chemotactic proteins that act as colonization factors allowing *V. cholerae* to adhere to the mucosal cell layers of the digestive tract, preventing the elimination of the pathogen.

Other virulence factors that contribute to pathogenesis is the enzyme sialidase, known as NanH or VcN, which remodels the GM1 toxin receptor, facilitating its binding by increasing the availability of this receptor.

Occlusive zonula toxin (zot) and cholera accessory enterotoxin (ace) are also involved. Occlusive zonula toxin increases intestinal membrane permeability by relaxing the junctional zones of the intestine, and cholera accessory enterotoxin increases fluid secretion, so the two complement each other (Chowdhury et al., 2017).

In general, cholera affects the entire population equally, although it is true that it is more serious in children, due to their smaller body volume, and their immune system has not fully matured, so therapeutic support is of vital importance to prevent death after hypovolemic shock that causes cholera. There are also certain characteristics of the host that can make it more susceptible to infection, so a person who has previously acquired the infection or has been vaccinated has some immunity, but this protection is specific to the serogroup and for *V. cholerae* O1 is dependent on the biotype and serotype.

In people suffering from achlorhydria problems are more likely to infection, since the pathogen is sensitive to gastric acids, and is an important defense barrier prior to colonization of the small intestine (Lippi et al., 2016).

As for the rest of the non-cholera-producing *Vibrio* species, the following virulence factors stand out.

V. parahaemolyticus produces a thermostable direct hemolysin (Vp-TDH) called Kanagawa, this enterotoxin produces the secretion of chloride ion, which is accompanied by fluid loss and causes watery diarrhea in the patient.

The action of enterotoxin can be seen by observing the beta-hemolysis produced by these strains when grown on a modified blood agar medium, called Wagatsuma-agar.

It has been proven that strains with this enterotoxin are responsible for the diarrhoeal clinical manifestations.

In addition to the presence of this toxin, there are others that collaborate in the virulence of the strain, they are called hemolysins related to Vp-TDH (Vp-TRH), and there are also strains carrying genes encoding type III secretion systems this virulence factor has been seen present in the main *Enterobacteria* causing diarrhea such as *Salmonella*, *Shigella* and *Enteropathogenic Escherichia coli*.

The pathogenicity mechanism of *V. vulnificus* involves several elements. It has polysaccharide capsule which gives it the ability to avoid phagocytosis by macrophages and evade the host immune response. Activates *cadC*, *cadB*, *cadA* genes that mediate *V. vulnificus* tolerance to gastric acid. Secretes cytotoxins, extracellular proteases (ECPase) and collagenase enzymes involved in tissue destruction. It has several adhesins that participate in bacterial adhesion, as well as protein U (OmpU) a protein present in the outer membrane and immunogenic lipoprotein A (LpA) both play the same function of adhesion; the latter also has immunogenic capacity and is involved in the activation of various signal transduction cascades (such as MAP kinases pathway) that activate different transcription factors of NF- κ B type and Toll-like receptors 1 and 2 which recognize various molecular patterns that are expressed by pathogens. All these elements are part of the innate immune system and by one mechanism or another causes the host to release a large amount of inflammatory mediators causing an exacerbated immune response (Yokochi et al., 2013).

Epidemiology

Vibrio is a pathogen found in various aquatic environments, able to withstand wide pH ranges and grow better in saline conditions. Asymptomatic patients can be considered reservoirs, since transmission is fecal-oral route, either through water or contaminated food such as crustaceans that inhabit these aquatic habitats. Person-to-person transmission is more complicated due to the high bacterial inoculum necessary to cause infection.

Cholera is a disease that occurs both endemically and epidemically. In South Asia and in some areas of Africa and Latin America, it is an endemic disease due to conditions of poverty and lack of sanitation and where access to safe drinking water is difficult. That is why this disease often emerges also after devastating natural events, in which conditions of poor sanitation, difficult access to safe food and inadequate sanitation are evident, as was recently the case after the earthquake in Haiti in 2010 and whose strain was subsequently linked to outbreaks in the countries of Cuba, Mexico and the Dominican Republic.

In countries where cholera is endemic, a seasonal course coinciding with peaks before and after rainy seasons can be observed; epidemic outbreaks are affected by climate the proliferation of *Vibrio* spp. is favored by warm temperatures and by population immunity.

In countries where they enjoy health resources, the cases that arise are imported cases of travelers from endemic or epidemic areas (Lekshmi et al., 2018; Chowdhury et al., 2017; Mutreja and Dougan, 2020).

According to WHO data, it is estimated that this disease affects approximately 1.3–4 million people, and between 21,000 and 143,000 deaths are due to this cause, although it is true that it is an under-diagnosed disease and morbidity and mortality data are not properly documented, so it is estimated that the actual number of cases is higher.

There is evidence of this disease throughout the 19th century, its original reservoir is located in India and from there, due to intercontinental travel, spread to the rest of the world. In history, a total of seven epidemics have been recorded, six due to *V. cholerae* O1 classical biotype and the seventh was caused by serotype O139, which began in Asia and spread to Africa and America.

Molecular epidemiology has allowed us to know that the current cholera pandemic is due to *V. cholerae* O1 El Tor which has displaced the classical biotype. The second wave of this pandemic differs because *V. cholerae* has acquired the antibiotic resistance gene SXT/R391 which encodes resistance to Trimethoprim/Sulfamethoxazole (Spagnoletti et al., 2014; Kiiru et al., 2009; Bordeleau et al., 2010).

For pathogenic *Vibrio* species other than cholera, such as *V. parahaemolyticus* and *V. vulnificus*, infection is due to consumption of crustaceans and shellfish exposed to contaminated water.

V. parahaemolyticus, like other *Vibrios*, is found in aquatic environments, and the increase in the number is favored by warm temperatures and salinity. Thus, it has been observed how global warming has affected the count of this microorganism in water.

In Japan and Southeast Asia this pathogen is the most frequent cause of bacterial diarrhea (Ndraha et al., 2020; Ndraha and Hsiao, 2021).

V. vulnificus is mainly associated with wound infections that can cause septicemia. It has regional and seasonal characteristics. Most of these infections occur in subtropical areas, and it is spreading to other regions as temperatures rise as a result of climate change that is affecting marine ecology. The peak of *V. vulnificus* infection is reached in summer and most cases occur from May to October coinciding with the fishing of fish and shellfish from fish farms, and with increased exposure to the sea by the population, which may have wounds that are the route of entry for the bacterium (Baker-Austin and Oliver, 2020).

Clinical illnesses

Vibrio cholerae

In *V. cholerae* infection we must distinguish between toxigenic *V. cholerae* (*V. cholerae* O1, *V. cholerae* O139) and *V. cholerae* non-O1, non-O139. In such a way that we can speak from asymptomatic colonization to gastrointestinal symptoms that compromise the patient's life.

V. cholerae O1, O139, is the causative agent of the disease called cholera, whose clinical manifestation is characterized by watery diarrhea. Symptoms begin after an incubation period of 3–5 days, abruptly with diarrhea and vomiting. The loss of liquid can be up to 1 L per hour, so as liquid is lost, the stool becomes colorless, which is why it is called "rice water stool." Due to the mechanism of pathogenicity of the bacteria, in which the loss of liquid is accompanied by loss of chloride and bicarbonate ions, which causes metabolic acidosis, and loss of sodium and potassium ions, this electrolyte imbalance causes muscle cramps, heart rhythm is affected, causing arrhythmias. Renal function and the nervous system are also compromised due to hypoperfusion of the organs.

The clinical features manifested by these patients are associated with the dehydration they suffer, without rapid rehydration. Thus, these patients present: thirst, irritability, lethargy, loss of skin turgor, decreased urine production, low blood pressure and sunken eyes.

Dehydration in its severe form causes hypovolemic shock in the patient, compromising the patient's life. It is of vital importance to establish a treatment of liquid and electrolyte replacement to avoid this outcome. Before rehydration therapy was established, cholera in its severe form could reach a mortality rate of 50% (Clemens et al., 2017).

Complications of cholera are infrequent, but the possibility of sepsis and aspiration pneumonia due to vomiting should be mentioned. Cases called "cholera sicca" have been described in which liquid accumulates in the intestinal lumen without causing diarrhea and circulatory collapse occurs.

Both *V. cholerae* serotypes O1 and O139 cause the same severe form of cholera, but they are clinically indistinguishable. *V. cholerae* non-O1, non-O139, do not produce cholera toxin, and cause mild diarrheal illness (Baker-Austin et al., 2018; Hsueh and Waters, 2019; Aydanian et al., 2015).

Vibrio parahaemolyticus

V. parahaemolyticus is responsible for gastrointestinal clinical manifestations, being diarrhea the most common symptom, but unlike that caused by *V. cholerae*, these are less serious for the patient. They are usually self-limited diarrhea and this infection is associated with the ingestion of contaminated raw seafood, mainly with the consumption of oysters, which involves greater risk, because they are water filters and accumulate higher concentrations of *V. parahaemolyticus*.

The gastrointestinal symptoms may be accompanied by other symptoms such as cramps, nausea and headaches, all of which are a consequence of hydrolytic loss (Martinez-Urtaza and Baker-Austin, 2020).

Vibrio vulnificus

V. vulnificus can present with a variety of clinical manifestations including primary septicemia following ingestion of contaminated raw seafood, secondary septicemia following infection of a wound exposed to contaminated water, traumatic wound infection and gastroenteritis.

Sepsis, whether primary or secondary, begins when the pathogen reaches the bloodstream. The patient will present with manifestations of sepsis including fever, chills and general malaise.

If the infection occurs via the digestive tract, this symptomatology may be accompanied by vomiting, diarrhea and abdominal pain. If the sepsis is due to a complication of the wound infection, this lesion presents tumefaction, blistering erythema, with exudation, cellulitis, tissue necrosis and muscle inflammation and finally the appearance of systemic signs.

In these septic conditions the mortality of these patients can be up to 50%. Within 24–48 h there may be a rapid evolution of symptoms reaching septic shock and multiple organ failure (Li and Wang, 2020; Baker-Austin and Oliver, 2020).

Diagnosis

The diagnosis of *V. cholerae* can be carried out by various techniques, although it is true that in most cases the clinical symptoms of the patient with diarrhea in "rice water" along with the anamnesis, will serve for the presumptive diagnosis, which will be confirmed by various microbiological tests.

Microscopy

Darkfield or fluorescence microscopy is used to observe small curved rods with polar flagellum and moving in the direct specimen. Microscopy is quite specific, but lacks sensitivity, so it is not appropriate to use it as the only diagnostic tool.

Culture

Vibrios are not species that need additional requirements, they grow well in the usual culture media used in microbiology laboratories, although it is true that selective media can be used as TCBS agar medium (Thiosulfate, Citrate, Bile, Sucrose), or tellurite taurocholate gelatin agar medium (TTGA) and enrichment broths as alkaline peptone water that allow a recovery of *Vibrio* in samples in which there are more microorganisms, as is the case of feces. Once the pathogen has been isolated, identification can be carried out by means of biochemical tests, and it will also allow the sensitivity study to be carried out. The serogroup and serotype can be determined using specific antisera by means of an agglutination reaction.

Nucleic acid amplification test (NAAT)

Genomic sequencing techniques, either of the whole genome or of highly conserved regions such as 16S rDNA and *rpoB* gene, have allowed to know the genome of the different species of *Vibrio*.

It is these techniques that have contributed to the knowledge of the different lineages. In such a way that it has allowed an expansion of knowledge in the field of molecular epidemiology.

It allows to establish the different relationships between species and to build the phylogenetic tree, which helps to understand the spread of the different pandemics and to know which strains have caused each one of them.

In addition, these techniques also allow to know the acquired genetic material responsible for antibacterial resistance, virulence genes and greater environmental stability of the different species.

Sequencing techniques have been used primarily for epidemiological research and surveillance (Liu et al., 2021; Yen et al., 2021).

Matrix-assisted laser desorption/ionization mass spectrometry (MALDI-TOF) is a powerful tool used in most microbiology laboratories for the identification of bacteria, fungi and yeasts. This technique allows the structural determination based on the mass/charge ratio (m/z) and the relative abundance (intensity) of the molecules that constitute the microorganism, which is represented by characteristic peaks.

MALDI-TOF identifies at genus level *Vibrio* spp. and at species level, from culture growth, without the need for biochemical tests which are more tedious techniques. The use of MALDI-TOF allows a fast and accurate alternative for colony identification. The appearance of different peaks that only appear in this genus, makes possible its typing thus distinguishing it from other closely related bacteria, such as species of the *Aeromonadaceae* family that also inhabit aquatic environments and are present in the same environment (Dieckmann et al., 2010; Cho et al., 2017; Cheng et al., 2015).

There are commercially available rapid techniques that can detect the presence of O1 and O139 antigens, allowing a diagnosis of *V. cholerae* in a direct sample that complements the diagnosis by culture, which is considered the gold standard.

It can also be identified by PCR, by quantitative real-time PCR (qPCR) techniques, which detect the DNA of the bacterial species, but not the viability of the species and thus the causative agent of the infection (Moussa et al., 2021).

Treatment, prevention and control

The main treatment in the case of cholera is water and electrolyte replacement; it is vitally important to hydrate the patient to avoid hypovolemic shock. This rehydration is usually done orally, but in severe cases intravenous administration is justified. Fluid management is carried out according to the degree of dehydration, which according to WHO criteria is classified according to the loss of fluid in relation to body weight:

- None if the loss is <5%.
- Medium if between 5% and 10%.
- Severe if >10%.

WHO recommends the use of oral rehydration salts (ORS), a standard sachet that dissolves in 1 L of drinking water and contains several vital electrolytes (sodium, potassium and chlorine) and a carbon source (glucose).

The administration of antibiotics to treat this disease is only advised in moderate-severe cases of cholera, since the massive administration of antibiotics will not interfere with the spread of cholera and will contribute to the emergence of bacterial resistance.

Antimicrobial treatment will be complementary with the aim of reducing the production of cholera toxin and therefore diarrhea, thus improving the clinical symptoms of these severe patients.

The empirical antibiotic of choice is usually Azithromycin, because resistance to this antibiotic is not common. Quinolones and tetracyclines can also be used, although it is true that the empirical use of these antibiotics is not the most advisable because resistance to these antibiotics is increasing and therapeutic failure may occur (Hsueh and Waters, 2019).

Due to the increase of antimicrobial resistance, it is important to perform antibiotic sensitivity studies, so that the choice of antibiotics will depend on the sensitivity profile of the microorganism and the type of patient to be treated. Likewise, it is recommended to periodically monitor the sensitivity in epidemic outbreaks in order to evaluate the possible emergence of resistance.

The determination of antimicrobial susceptibility can be performed by the disc diffusion method or E-test, and also by broth microdilution.

Antibiotics generally tested for *V. cholerae* are: tetracyclines (whose result can be extrapolated to Doxycycline), Trimethoprim/Sulfamethoxazole, Ampicillin (representative for Amoxicillin), Chloramphenicol, Nitrofurantoin, Ciprofloxacin, and Azithromycin.

For *Vibrio* spp. third generation cephalosporins (Cefotaxime, Ceftazidime) can also be used.

Also, it is revealing to know the serotype and biotype of *V. cholerae*, because most *V. cholerae* O139 and *V. cholerae* O1 El Tor are usually resistant to Trimethoprim/Sulfamethoxazole, which is another therapeutic alternative (Janda et al., 2015).

In the case of gastroenteritis caused by *Vibrio haemolyticus*, it is usually self-limiting, and like cholera, the main treatment is fluid and electrolyte replacement, and in severe cases antibiotics are added to the treatment regimen.

In clinical manifestations, in which *V. vulnificus* is involved, in wound infections and septicemia, should be treated early with appropriate antimicrobial treatment according to sensitivity studies. In general, the use of tetracyclines and/or third generation cephalosporins is recommended, to which quinolones can be associated. Depending on the resistance profile of each country, one or other antibiotics will be used as the first line of treatment.

In cases of traumatic infection, surgical debridement of the wound is very important and on extreme occasions it may be necessary to amputate the affected limb if the tissue necrosis is too severe, all in order to improve the patient's prognosis.

The main prevention is an improvement of sanitary conditions, water potabilization, good control of waste, sewage and the introduction of measures to avoid food contamination. In cases of travelers to endemic areas, the use of bottled water and avoidance of raw or undercooked seafood are recommended (George and Sack, 2017). In cases of *V. vulnificus* infection, which is highly lethal, it is very important to avoid exposure to seawater and consumption of raw seafood. And upon suspicion and appearance of clinical signs, early antibiotic treatment is essential (Park and Lee, 2018).

In addition to these essential measures, there are also oral vaccines that reduce the risk of contracting cholera and attenuate the effects of the infection, and these vaccines are intended not only to immunize the population but also to reduce transmission. As oral vaccines, the aim is to achieve immunity at the mucosal level of the intestine, preventing colonization and multiplication of *V. cholerae*.

There are two types of oral vaccines, inactivated vaccines, which contain whole killed *V. cholerae* cells, and live attenuated vaccines, which contain genetically modified strains of *V. cholerae* that are not pathogenic. The latter are usually single-dose vaccines as opposed to killed-cell vaccines that require two or three doses over an interval of time.

Inactivated vaccines have reduced efficacy in children under 5 years of age, who are usually the most vulnerable population. In contrast, live attenuated vaccines confer greater immunity, as they mimic infection by producing antigens and colonization factors, which are targets of protective immunity. Despite this, these vaccines have not been approved for use in cholera-endemic regions (Shaikh et al., 2020; Sinclair et al., 2011).

The following vaccines are currently available on the market:

- Wc-rBS (Dukoral®): Monovalent inactivated vaccine, contains whole killed cells of *V. cholerae* O1 and the recombinant B fraction of the cholera toxin. It is administered in a buffered solution to prevent degradation of the B subunit by the action of gastric acid. This complicates the logistics of administering the vaccine, as well as its storage and shipment to vaccination sites.
- BivWC (Shanchol®) bivalent inactivated vaccine, containing killed cells of *V. cholerae* O1 and O139. This vaccine lacks the recombinant B subunit in order to facilitate administration by avoiding buffer solution and also to reduce vaccine costs. This vaccine was reformulated from the mORCVAX® vaccine and allowed its purchase by the ONU agency, fulfilling the requirements of the WHO.
- Euvichol-Plus®: It is the same as the Shanchol® vaccine, the manufacturing competences were transferred to the company Eubiotics, in order to be able to supply the demand in the population.
- BivWC (mORCVAX®) is identical to the Shanchol® vaccine, but is only available in Vietnam.
- Vaxchora®: Monovalent live attenuated vaccine, single dose, which is indicated for immunization against *V. cholerae* O1. Exposure to attenuated strains of *V. cholerae*, causes an increase in antibody titer against *V. cholerae*, thus generating some immunity and protection against future infections.

It is only marketed in the United States and is indicated for use in travelers to endemic areas, in order to reduce the risk of infection (Mosley et al., 2017).

Infections due to *Pseudomonas* spp. are caused by members of the genus *Pseudomonas*, from the family Pseudomonadaceae, a group of gram-negative rods. The genus *Pseudomonas* encompasses more than 140 species, which inhabit a variety of niches in soil and water. Several species of *Pseudomonas* may cause infection in humans (Table 1); but, by far, the most frequently recovered pathogen in the family is *P. aeruginosa* (D'Agata, 2015; Falagas and Rafailidis, 2020).

Related gram-negative bacillary diseases include infections due to *Stenotrophomonas maltophilia* (formerly known as *Pseudomonas maltophilia* and *Xanthomonas maltophilia*), *Ralstonia pickettii* (formerly *Pseudomonas*, then *Burkholderia pickettii*), *R. mannitolilytica* (formerly *Pseudomonas thomasi*, then *R. pickettii* biovar 3/"thomasi") and members of the genus *Burkholderia* (formerly *Pseudomonas*, then *B. pseudomallei*, *B. mallei*, and *B. cepacia* complex) (Currie, 2015; Falagas and Rafailidis, 2020; Steinberg and Burd, 2015). This article refers only to infections caused by *Pseudomonas* spp.

Microbiology

Pseudomonas aeruginosa is a gram-negative, obligate aerobic, lactose nonfermenting, straight or slightly curved rod with a length ranging from 1 to 3 µm and a width of 0.5–1.0 µm (D'Agata, 2015; Falagas and Rafailidis, 2020). It is catalase positive, oxidase positive, and motile with one or more polar flagella. Most species oxidize glucose and reduce nitrate to nitrite or nitrogen gas. The exterior surface of this pathogen consists of a polysaccharide capsule with lipopolysaccharides, pili and polar flagella. Furthermore, it is capable of elaborating a large number of toxins. On culture plates, *P. aeruginosa* grows at 37–42 °C, forming smooth round colonies with a characteristic sweet grape-like odor and a typical green-blue coloration. This coloration is due to the production of pigments, notably a pigment called pyocyanin (blue) and pyoverdine (green or yellow-green). In fact, the name "*aeruginosa*" derives from the green-blue hue seen in colonies of many clinical isolates. However, some strains produce red or black colonies because of the synthesis of the pigments termed pyorubin and pyomelanin, respectively. Isolates from patients with cystic fibrosis and other chronic infections may have a distinct mucoid appearance (Pang et al., 2019; Kanj and Sexton, 2019d). This is the consequence of the overproduction of an extracellular polysaccharide known as alginate. *Pseudomonas* strains with acquired resistance to multiple antibiotics have become common in some hospitals and regions (Del Barrio-Tofiño et al., 2019; Falagas and Rafailidis, 2020).

Epidemiology

P. aeruginosa is ubiquitous in nature and it can be found in most fresh water environments (Kanj and Sexton, 2019d). Apart from infecting humans, *P. aeruginosa* is also an important plant pathogen, affecting tobacco, tomatoes, and lettuce (Kanj and Sexton, 2019d). This organism can survive in environments with minimal nutrients. Colonization by *P. aeruginosa* in human usually takes place in moist areas, such as perineum, auditory canal, axillae, and the lower alimentary canal. It is also isolated from other moist, inanimate environments within the hospital, including sink traps and drains, toilets, showers, ice machine, kitchen settings, cleaning mops, water in vases of flowers, and even cleaning solutions. It can become a particular problem when it contaminates multidose medications or medical devices with a moist environment including endoscopes, ventilators, pressure monitors, dialysis equipment, and the like (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019d).

P. aeruginosa is often an opportunistic pathogen, causing infections in patients with physical, phagocytic, or immunologic defects in host mechanisms. Thus, this organism is one of the most common pathogens in health care-associated infections. According to data reported to the National Healthcare Network at the Centers for Disease Control and Prevention in the United States from 2011 to 2014, *P. aeruginosa* was the sixth most common cause of hospital-acquired infections in general (7.3%); the second most common cause of ventilator-associated pneumonia (16.5%); and the third most common cause of urinary tract infections associated with urinary indwelling catheter (10.3%) (Weiner et al., 2016). Ventilator-associated pneumonia, primary bacteremia associated with intravenous catheters or secondary bacteremia in relationship to infections at different sites of the body, urinary tract infections, and surgical site infections are the main types of infections caused by *P. aeruginosa* in the hospital setting (Falagas and Rafailidis, 2020).

A range of hosts are particularly prone to infections by this pathogen. Historically, patients with neutropenia, burns, and cystic fibrosis (CF) were considered especially susceptible to infections by this organism (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019d). However, for unknown reasons the incidence of *Pseudomonas* infections in all these patients is decreasing in Western Europe and North America (Kanj and Sexton, 2019d). Nonetheless, *P. aeruginosa* remains the most common pathogen isolated from adults with CF (Kanj and Sexton, 2019d). It is also the most common cause of respiratory failure in CF and is responsible for the deaths of the majority of these patients. In addition, a study from Spain has shown that *P. aeruginosa* was the most common cause of gram-negative bacteremia among neutropenic patients with malignancy and pneumonia (Gudiol et al., 2016).

In CF patients, acquisition of *P. aeruginosa* begins early in childhood (median 1 year); and the initial acquisition is with nonmucoid strains (Kanj and Sexton, 2019d). Over time (median 11 years), there is a transition to a mucoid phenotype of *P. aeruginosa* that is associated with a deterioration in symptoms, chest X-ray and pulmonary function in these patients. Furthermore, Oliver et al. (2000) have demonstrated that patients with CF are colonized with hypermutable strains of *P. aeruginosa* which may persist for years in the respiratory tree of these patients.

Other patients prone to *P. aeruginosa* infection include patients with compromised immunity (cancer patients, transplant recipients, diabetics, and patients with AIDS) and patients with foreign bodies (e.g., vascular grafts, orthopedic implants) (Falagas and Rafailidis, 2020).

Infection due to *P. aeruginosa* is characteristically nosocomial. Notwithstanding, there has been increasing recognition of *P. aeruginosa* as a cause of community-acquired infections (Kanj and Sexton, 2019d). In the nonhospital setting, pseudomonas infection is related to exposure to the water of recreational baths (swimming pools, whirlpools, hot tubs, spas), as well as to the use of contact lenses, particularly the extended-wear variety (Falagas and Rafailidis, 2020). Puncture wounds, including those through contaminated trainers, can give rise to *P. aeruginosa* osteomyelitis of the foot. *P. aeruginosa* endophthalmitis after eye trauma can result in visual compromise, and *P. aeruginosa* endocarditis can be found in intravenous injection drug users (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019d).

Clinical manifestations

P. aeruginosa possesses a vast array of virulence factors. Some studies have pointed out that certain virulence factors may be related to infection severity (Peña et al., 2015). As mentioned earlier, *Pseudomonas* may produce varied clinical manifestations; and no symptoms or signs effectively allow to discriminate *Pseudomonas* infection from infections caused by other pathogens.

Febrile neutropenia

P. aeruginosa is an important pathogen causing infection in patients with neutropenia. The classic clinical syndromes in febrile neutropenic patients are bacteremia, pneumonia, and soft tissue infection, typically manifested as ecthyma gangrenosum (see later). Mortality rate increases if appropriate treatment of infection is delayed. Thus, *P. aeruginosa* is the organism against which empirical coverage must always be included in neutropenic patients with fever (Falagas and Rafailidis, 2020).

Bacteremia

Pseudomonas aeruginosa bacteremia usually occurs in patients with serious underlying diseases and presents a high mortality rate. The great majority of reported crude mortality rates from large surveillance studies range from 39% to 60% (D'Agata, 2015); although recent studies report lower mortality rates around 30% (Peña et al., 2015; Babich et al., 2019). The large range in mortality rates from different studies reflects the multitude of factors that affect outcomes associated with blood stream infections (D'Agata, 2015). Risk factors for mortality in *P. aeruginosa* bacteremia include advanced age, high APACHE II score, sepsis, poor functional status, polymicrobial bacteremia, and inappropriate initial antimicrobial treatment (D'Agata, 2015; Kanj and Sexton, 2019c). It usually derives from primary infection at different sites, such as pneumonia, urinary tract infection, complicated intra-abdominal infection (peritonitis, abscess), and endocarditis. The source of the bacteremia may be unknown in up to 40% of cases (Kanj and Sexton, 2019c). Manifestations can include those of sepsis and septic shock; that is, fever, tachycardia, tachypnea, hypotension, and mental status changes ranging from confusion to coma. Multiorgan failure with adult respiratory distress syndrome and acute renal failure along with coagulation defects may occur (Kanj and Sexton, 2019c).

Infective endocarditis

P. aeruginosa may cause infective endocarditis (IE), mainly of native valves but also of prosthetic ones. Complications are common, and mortality rates are high, ranging from 36% to 60% (D'Agata, 2015). In earlier years, more than 90% of cases of IE due to *P. aeruginosa* had been reported in intravenous drugs users (IDU) (Kanj and Sexton, 2019c). Nonetheless, IDU was recognized in only 4% of cases of IE caused by non-HACECK Gram-negative aerobic bacilli in a multinational survey that included 49 patients seen between 2000 and 2005 (Baddour et al., 2015). The majority of IDU with pseudomonal IE had used tripeleminamine and pentazocine with contaminated water or paraphernalia (D'Agata, 2015; Kanj and Sexton, 2019c). Patients predominantly present with right-sided endocarditis; and the clinical manifestations of *P. aeruginosa* endocarditis resemble those of other forms of acute endocarditis in addicts (Falagas and Rafailidis, 2020). *P. aeruginosa* left-sided endocarditis occurs also in non-intravenous injection drug users, although infrequently. It is predominantly a nosocomial infection occurring after invasive procedures (D'Agata, 2015).

Ventilator-associated pneumonia and hospital acquired pneumonia

The respiratory tract is a frequent site of infection due to *P. aeruginosa*. This microorganism can occasionally cause community-acquired pneumonia; but it is a well-established cause of hospital exposure pneumonia, either associated with or without mechanical ventilation (D'Agata, 2015; Kanj and Sexton, 2019e). It is the second most common pathogen involved in ventilator-associated pneumonia (VAP) after *Staphylococcus aureus*; and it causes 9% of all episodes of nosocomial pneumonia among non-ventilated patients (D'Agata, 2015). According to the definitions by the 2016 Infectious Diseases Society of America and American Thoracic Society, hospital acquired pneumonia is defined as pneumonia not incubating at the time of hospital admission, and occurring 48 h or more after admission, and not associated with mechanical ventilation (Kalil et al., 2016). VAP is a pneumonia occurring >48 h after endotracheal intubation. The clinical manifestations of *P. aeruginosa* pneumonia are similar to infections caused by other microorganisms.

Currently, the evidence suggests that outcomes for pneumonia are similar regardless of whether respiratory specimens are obtained invasively or noninvasively, and whether microbiologic cultures are performed quantitatively or semiquantitatively. Therefore, the etiologic diagnosis in patients with nosocomial pneumonia should be pursued through noninvasively obtained respiratory samples with semiquantitative cultures (Kalil et al., 2016) (see Diagnosis).

Chronic respiratory tract infections

P. aeruginosa is responsible for chronic colonization of the airways associated mainly with CF, advanced chronic obstructive pulmonary disease and bronchiectasis (D'Agata, 2015; Eklof et al., 2020; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019d,

e). In these cases, recurrent pneumonia may ensue. Another chronic infection of the respiratory tract associated with *P. aeruginosa* is diffuse panbronchiolitis, which mainly affects Asian populations (Falagas and Rafailidis, 2020).

Urinary tract infections

Urinary tract infections (UTIs) due to *P. aeruginosa* are typically hospital acquired (Kanj and Sexton, 2019a). *P. aeruginosa* is the third most common pathogen to cause hospital acquired UTIs, after *Escherichia coli* and *Enterococcus* spp. (Kanj and Sexton, 2019a). Pseudomonal UTIs usually occur as a complication of the presence of a foreign body, such as a catheter or stent in the urinary tract, or an obstruction (mainly a stone or malignant neoplasm) of the urinary system, or after instrumentation or surgery in the urinary tract (Fig. 1). For patients with a chronic indwelling bladder catheter, the isolation of *P. aeruginosa* is not necessarily indicative of a UTI, since bacteriuria and even pyuria in the absence of overt infection are common in such settings (Kanj and Sexton, 2019a). Notwithstanding, there have been descriptions of *P. aeruginosa* UTIs in outpatient children and adults without relevant evidence of urinary tract obstruction or foreign bodies (Falagas and Rafailidis, 2020). Urinary tract infection is frequently a source for bacteremia.

Eye infections

P. aeruginosa may produce eye infections, generally in relationship with eye trauma or surgery. Corneal infections caused by *P. aeruginosa* may manifest as focal or diffuse inflammation of the cornea (keratitis) or as corneal ulcers (Kanj and Sexton, 2019a). Pseudomonas causes a virulent form of keratitis which predominantly appears in subjects who wear contact lenses (Kanj and Sexton, 2019a; Puig et al., 2020). Clinical findings of keratitis include eye redness, pain and decreased visual acuity. Perforation of the cornea may occur and the disease can progress quickly and lead to loss of vision.

Endophthalmitis is another *P. aeruginosa* eye infection that may result from penetrating injuries, surgery, perforation of a corneal ulcer, or seeding from bacteremia (Kanj and Sexton, 2019a). The course of pseudomonal endophthalmitis is typically fulminant, developing over hours (Kanj and Sexton, 2019a). The initial symptom is decreased vision followed by dull severe ocular pain. Other findings include chemosis, conjunctivitis, lid edema, anterior uveitis and vitritis (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019a).

Orbital cellulitis and gangrene necrosis of the eyelids have rarely been reported in neutropenic patients as metastatic foci of bacteremia (Falagas and Rafailidis, 2020).

Ear infections

P. aeruginosa causes acute external otitis, chronic otitis media, and malignant external otitis (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019a). Acute external otitis due to *P. aeruginosa* is common in swimmers, mostly in residents of warm or

Fig. 1 Urinary cast from a nephrostomy tube. A 55-year old woman presented with right ureteral-hydronephrosis after gynecologic surgery. A percutaneous placement of a nephrostomy tube into the right dilated renal pelvis was carried out. The patient had high fever and right costovertebral angle pain. Cultures from urine and blood yielded *P. aeruginosa*. She eliminated a cast into the urine bag which accommodated to the form of the nephrostomy tube. The nephrostomy tube was removed and the patient was treated with antibiotics. Courtesy of Dr. A. Ceballos.

humid climates ("swimmer's ear"). The source of the organism is likely to be insufficiently chlorinated water from hot tubs or swimming pools. Patients with external otitis typically complain of ear itching and pain (otalgia), worsened by traction on the pinna. On examination, the external auditory canal is usually tender, edematous and contains debris. The infection is usually self-limited without sequelae. In chronic otitis media caused by *P. aeruginosa*, the main clinical manifestation is fluid discharge. Cultures are usually polymicrobial; although *P. aeruginosa* is found in isolation in a third of patients.

Malignant external otitis is a life-threatening *Pseudomonas* infection, which particularly affects elderly patients with diabetes (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019a). Malignant otitis occurs when *P. aeruginosa* penetrates the epithelium of the external auditory canal and invades the surrounding soft tissue, cartilage and cortical bone. Infection can spread to the retromandibular, parotid and mastoid spaces, and even to the bones of the base of skull (skull base osteomyelitis). Infection presents with pain and discharge from the affected ear, sometimes accompanied by fever and hearing loss. Cranial nerve palsies (VI–XII) appear later in the course. Altered mental status may be seen, indicating the spread of infection into the brain, which heralds an ominous clinical course. Prompt diagnosis and treatment of this condition is essential. Cultures specimens should be taken from the ear canal and neuroimaging should be performed (computed tomography or magnetic resonance imaging). Gallium scan may be used to evaluate the bone extension of the disease.

Bone and joint infections

P. aeruginosa is a common cause of bone infections in patients with indwelling devices or prosthesis used in orthopedics and neurosurgery (D'Agata, 2015; Falagas and Rafailidis, 2020). Furthermore, vertebral osteomyelitis, sacroiliac septic arthritis, and sternoclavicular septic arthritis have been well documented in IDU (D'Agata, 2015; Falagas and Rafailidis, 2020). Sternoclavicular and sacroiliac septic arthritis from *P. aeruginosa* is seen almost exclusively in IDU. Before 1981, *P. aeruginosa* sternoclavicular septic arthritis was related with the injection of tripeleminamine and pentazocine (D'Agata, 2015). These infections are the result of bacteremia secondary to either injection of contaminated illicit drugs or IE. The clinical manifestations of vertebral *P. aeruginosa* osteomyelitis are more indolent than those of staphylococcal osteomyelitis. Patients present after 1–3 months of symptoms, which include neck or back pain, with fever present in fewer than half (D'Agata, 2015).

Pseudomonas osteomyelitis of the foot may follow nail puncture wounds to the plantar surface and inoculation of the pathogen through contaminated trainers. Most of these cases are reported in children, but it is also seen in adults. The main manifestation is pain in the foot and there may be superficial cellulitis around the puncture wound. *P. aeruginosa* also has the potential to affect the diabetic foot, especially when there is frequent exposure to water (Falagas and Rafailidis, 2020).

Central nervous system infections

Intracranial infections caused by *Pseudomonas* are rare clinical events. They appear following penetrating head trauma or neurosurgery and most patients have serious underlying diseases (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019a). The entities seen most often are postoperative or post-traumatic meningitis, subdural empyema, and epidural infections resulting from initial contamination of access areas or wounds. Brain abscess secondary to embolic disease from endocarditis has also been described in drug addicts. Clinical features and diagnosis are similar to central nervous system infections caused by other gram-negative pathogens.

Skin and soft tissue infections, including burns

Ecthyma gangrenosum is a characteristic manifestation of *P. aeruginosa* bacteremia among immunocompromised patients, especially those with neutropenia (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019b). It has been observed in approximately 1.3–3% of *P. aeruginosa* bacteremia cases (Kanj and Sexton, 2019b). Ecthyma gangrenosum, however, can also be caused by numerous other bacteria (including *S. aureus* and *Citrobacter freundii*), fungi, and viruses, and has also been documented to occur among immunocompetent hosts, but with much lower incidence; and even, in the absence of bacteremia (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019b). However, the presence of this skin lesion should raise high suspicion for *P. aeruginosa* bacteremia (D'Agata, 2015). Ecthyma lesion results from perivascular bacterial invasion of the tunica media and adventitia of arteries and veins with secondary ischemic necrosis (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019b). Lesions begin as single or multiple red macules progressing to vesicles and later bullous or pustular lesions. Hemorrhage and necrosis in the central part ensues, followed by the development of a grey-black eschar with surrounding erythema, within 12–18 h (Fig. 2). All body parts can be involved, but the anogenital and axillary areas are most commonly affected (D'Agata, 2015; Kanj and Sexton, 2019b). On histology, there is epidermal and upper dermal necrosis, inflammatory cell infiltrate, necrotizing vasculitis and vascular thrombosis. *P. aeruginosa* is isolated from skin biopsy specimens and blood (D'Agata, 2015; Kanj and Sexton, 2019b).

Complication of burn injuries by *P. aeruginosa* skin infection is a severe and significant problem (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019b). Patients present an expanding black necrotic eschar along with a high colony count of *P. aeruginosa* of exceeding 10^5 organisms per gram of skin tissue (Falagas and Rafailidis, 2016; Kanj and Sexton, 2019b). Signs of sepsis may be present.

Fig. 2 Ecthyma gangrenosum in 21-year-old woman with acute myeloid leukemia. The lesion started on her left knee after 5 days of chemotherapy, as a painless erythematous macule (A), which progressed rapidly into a violaceous pustule (B). Blood and wound cultures grew *P. aeruginosa*. From Korte AKM and Vos JM (2017) Ecthyma gangrenosum. *The New England Journal of Medicine* 377: e32, with permission from the Publisher.

Paronychia is the acute or chronic inflammation of the proximal and lateral nail folds. *P. aeruginosa* can cause acute or chronic paronychia. In these cases, the affected digit is painful and swollen with pus discharge localized to one corner of the proximal nail fold. Green nail syndrome is an extension of chronic paronychia with a bluish-green discoloration of the nail plate, due to the diffusion of pyocyanin and pyoverdine produced by *Pseudomonas* spp. through the nail bed (Kanj and Sexton, 2019b).

Hot tub folliculitis is an infection of the infundibulum (upper segment) of the hair follicle, just beneath the skin surface, caused by *P. aeruginosa* (D'Agata, 2015). It is a recreational skin infection associated with immersion in contaminated swimming pools, hot tubs, and whirlpools (D'Agata, 2015; Kanj and Sexton, 2019b). The main presentation is that of a maculopapular superficial folliculitis that is painful and pruritic and that becomes vesiculopustular within 24–48 h after exposure. It remits spontaneously within 7–14 days.

Intra-abdominal and gastrointestinal infections

P. aeruginosa may be involved in complicated intra-abdominal infections. It may be recovered (in isolation or as part of a polymicrobial flora) in secondary and tertiary peritonitis, intra-abdominal abscesses and peritonitis associated with continuous ambulatory peritoneal dialysis (Falagas and Rafailidis, 2020). Necrotizing enterocolitis due to *P. aeruginosa* in children, mainly from Taiwan and China (Shanghai fever), and typhlitis in neutropenic patients have also been described (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019a).

Infection due to *Pseudomonas* spp. other than *Pseudomonas aeruginosa*

Infection due to other *Pseudomonas* spp. may occur, usually among immunocompromised hosts (D'Agata, 2015; Falagas and Rafailidis, 2020) (see Table 1). The great majority of strains are susceptible to third-generation cephalosporins, piperacillin, carbapenems, and fluoroquinolones. However, antimicrobial susceptibility patterns should always guide therapy (D'Agata, 2015).

P. fluorescens belongs to the fluorescens group of *Pseudomonas* species, along with *P. aeruginosa* and *P. putida*. *P. fluorescens* has been implicated in catheter-related bloodstream infections and in some outbreaks related to blood transfusions and other contaminated fluids (D'Agata, 2015; Falagas and Rafailidis, 2020). *P. putida* has been reported as a causative pathogen in bacteremia, pneumonia, cholecystitis, cholangitis, urinary tract infections, and war wounds. Reports of *P. stutzeri* infections include osteomyelitis, arthritis, bacteremia, endocarditis, endophthalmitis, pneumonia, empyema, urinary tract infections, and meningitis. Species of *Pseudomonas* other than the aforementioned have only been documented as a human pathogen in isolated case reports (D'Agata, 2015).

Diagnosis

From a clinical stand point, there are no symptoms or signs to distinguish *Pseudomonas* infection from diseases caused by other pathogens. However, some epidemiological data should be a clue to consider *P. aeruginosa* as the causative organism of infection. Clinicians should consider *Pseudomonas* infections in the differential diagnosis of hospital-acquired infections and in specific population of patients, such as neutropenic patients, patients with burns, CF patients, and external otitis in diabetics.

Obviously, the etiologic diagnosis of infectious diseases implies the culture isolation of the pathogen from pertinent clinical samples. Moreover, newer methods, including multiplex polymerase chain reaction (PCR) tests, which are based on the detection of the bacterial DNA, have received clearance from the Food and Drug Administration (FDA) for use in clinical practice. PCR offers the advantage of speed in diagnosis. Serology is not helpful in the diagnosis of *P. aeruginosa* infections. Pulsed-field gel electrophoresis, restriction fragment length polymorphism, multilocus sequence typing, and random amplified polymorphic DNA PCR are used mainly for epidemiologic purposes (Falagas and Rafailidis, 2020).

For the diagnosis of IE, the American Heart Association recommends three blood culture sets, obtained from different venipuncture sites, with the first and last drawn at least 1 h apart and early echocardiography (Baddour et al., 2015). In patients with VAP, endotracheal aspiration with semiquantitative microbiologic culture is currently preferred over invasive sampling (bronchoscopy for bronchoalveolar lavage or obtaining samples through a protected specimen brush or blind bronchial sampling [mini-BAL]) and quantitative culture to diagnose pneumonia (Kalil et al., 2016). In non-ventilated patients with hospital acquired pneumonia, non-invasively obtained samples (expectorated sputum, induced sputum or nasotracheal suctioning) and semiquantitative culture are also preferred (Kalil et al., 2016). For the etiologic diagnosis of osteomyelitis, the acquisition of bone through fine-needle aspiration guided by CT or open bone biopsy is necessary when blood cultures are sterile (Falagas and Rafailidis, 2020; Osmon et al., 2013).

A challenge clinicians face frequently is to differentiate frank infection due to *P. aeruginosa* from colonization. Local or systemic symptoms and signs of infection along with clinical judgment may aid to resolve this difficult dilemma.

Treatment

General principles

P. aeruginosa is intrinsically resistant to many antibiotics and can acquire resistance to other agents during therapy. This happens either by selection of mutations in chromosomal genes and from the growing prevalence of horizontal gene transfer (Del Barrio-Tofiño et al., 2019; Falagas and Rafailidis, 2020). Antibiotics used to treat *P. aeruginosa* infections belong to eight categories, including aminoglycosides (gentamicin, tobramycin, amikacin, netilmicin), carbapenems (imipenem, meropenem, doripenem), cephalosporins (ceftazidime, cefepime), fluoroquinolones (ciprofloxacin, levofloxacin), antipseudomonal penicillins plus beta-lactamase inhibitors (ticarcillin-clavulanic acid, piperacillin-tazobactam), monobactams (aztreonam), fosfomycin, and polymyxins (colistin, polymyxin B). Attending to these categories and antimicrobials, Magiorakos et al. (2011) standardized definitions for acquired antimicrobial resistance of *P. aeruginosa*, as multi-drug resistant (MDR), extensively-resistant (XDR), and pandrug resistant (PDR). PDR is a strain non-susceptible to all antimicrobial agents mentioned above. XDR is an isolate non-susceptible to ≥ 1 agent in all but ≤ 2 categories. MDR is a *P. aeruginosa* strain non-susceptible to ≥ 1 agent in ≥ 3 antimicrobial categories. In Spain, a recent nationwide survey on *P. aeruginosa* resistance has shown a high resistance rate for most antipseudomonal antibiotics (Table 2) (Del Barrio-Tofiño et al., 2019). In this study, 26% of the isolates were classified as MDR, 17% as XDR, and 0.1% as PDR. Patterns of antibiotic resistance in *P. aeruginosa* evolve over time and vary geographically and by type of infection (Del Barrio-Tofiño et al., 2019; Fernández-Cuenca et al., 2020; Kanj and Sexton, 2020; Weiner et al., 2016). This geographical variation highlights the importance of local data when choosing empiric therapy. Appropriate antibiotics for *P. aeruginosa* treatment and their dosages, provided the renal clearance is >50 – 60 mL/min, are shown in Table 3.

Antipseudomonal penicillins in combination with a β -lactamase inhibitor include piperacillin-tazobactam and ticarcillin-clavulanate. Tazobactam inhibits AmpC-type β -lactamases but does not have direct antipseudomonal activity (Kanj and Sexton, 2019d). Recently, newer beta-lactamase inhibitor combinations have been introduced. These compounds include ceftazidime-avibactam, ceftolozane-tazobactam, imipenem-cilastatin-relebactam, meropenem-vaborbactam, and aztreonam-avibactam. Neither varbobactam nor avibactam enhance the bacterial activity of meropenem and aztreonam against carbapenem resistant *P. aeruginosa* (Bassetti et al., 2018; Morris and Cerceo, 2020; Kanj and Sexton, 2019d). Imipenem-cilastatin-relebactam is a novel

Table 2 Antimicrobial susceptibility data for 1445 *P. aeruginosa* isolates according to EUCAST 2018 breakpoints.

Antibiotic	Susceptible (%)	Resistant (%)
Ticarcillin	18.8	81.2
Ceftazidime	79.7	20.3
Cefepime	79.4	20.6
Piperacillin-tazobactam	73.5	26.5
Ceftolozane-tazobactam	94.6	5.4
Ceftazidime-avibactam	94.2	5.8
Aztreonam	–	14.8
Imipenem	72.8	15.6
Meropenem	70.1	14.1
Ciprofloxacin	61.6	38.4
Tobramycin	83.7	16.3
Amikacin	91.6	4
Colistin	94.6	5.4

Modified from Del Barrio-Tofiño E, Zamorano L, Cortes-Lara S, et al. (2019) Spanish nationwide survey on *Pseudomonas aeruginosa* antimicrobial resistance mechanisms and epidemiology. *Journal of Antimicrobial Chemotherapy* 74: 1825–1835.

Table 3 Intravenous antibiotics effective against *Pseudomonas aeruginosa* infections in adults (D'Agata, 2015; Falagas and Rafailidis, 2020; Kalil et al., 2016; Kanj and Sexton, 2019c, 2019d; Morris and Cerceo, 2020).

Class	Agent	Dose ^a
Penicillin-beta-lactamase combinations	Ticarcillin-clavulanate	3.1 g q 4 h
	Piperacillin-tazobactam	4.5 g q 6 h ^b
Cephalosporins	Ceftazidime	2 g q 8 h
	Cefepime	2 g q 8 h or q 12 h
	Cefoperazone	2 g q 12 h
	Cefiderocol	2 g q 8 h
Advanced beta-lactamase inhibitor combinations ^c	Ceftazidime-avibactam	2.5 g q 8 h
	Ceftolozane-tazobactam	1.5–3 g q 8 h ^d
	Meropenem-vaborbactam	4 g q 8 h (infused over 3 h)
	Imipenem-relebactam	1.25 g q 6 h (infused over 30 min)
Monobactams	Aztreonam ^e	2 g q 8 h
Fluoroquinolones	Ciprofloxacin	400 mg q8
	Levofloxacin	750 mg q 24 h
Carbapenems ^f	Imipenem	500 mg q 6–8 h ^g
	Meropenem	1 g q 8 h
	Doripenem	500 mg q 8 h
Aminoglycosides ^h	Tobramycin	5–7 mg/kg q 24 h
	Gentamicin	5–7 mg/kg q 24 h
	Amikacin	15–20 mg/kg q 24 h
Polymyxins ⁱ	Colistin	6–9 MU loading dose then 4.5 MU q 12 h (maintenance dose) OR 5 mg/kg loading dose then 2.5 mg × (1.5 × CrCl +30) q 12 h (maintenance dose)
	Polymyxin B	2.5–3 mg/kg q 24 h divided in two daily doses
Phosphonic antibiotic ^j	Fosfomycin	16–24 g q 24 h in 3–4 divided doses

^aDoses are for intravenous administration. Doses listed are for patients with normal renal function; dose adjustments may be warranted for renal impairment.

^bPiperacillin-tazobactam is generally infused over 30 min. Some evidence suggests that an extended infusion (4.5 g over 4 h every 8 h) may be associated with better outcomes among critically ill patients.

^cCombinations agents that include a cephalosporin or carbapenem plus a β -lactamase inhibitor are generally reserved for specific types of infections (such as complicated intra-abdominal or complicated urinary tract infection) resistant to other agents.

^dPulmonary infections are treated with the 3 g every 8 h dose.

^eIn the absence of other options, it is acceptable to use aztreonam as an adjunctive agent with another β -lactam-based agent because it has different targets within the bacterial cell wall.

^fCarbapenems given as a single therapy have the propensity to induce resistance during treatment.

^gImipenem can be given up to a dose of 1 g every 6–8 h for severe infection.

^hAminoglycosides are generally used in combination with a beta-lactam and should NOT be used as a single agent for pseudomonal infections other than those of the lower urinary tract. When using an aminoglycoside as part of therapy for an infection with *P. aeruginosa*, some authorities prefer tobramycin over gentamicin because the former seems to have greater intrinsic antipseudomonal activity; however, other experts favor amikacin.

ⁱPolymyxins are generally reserved for the treatment of serious infections caused by *P. aeruginosa* isolates resistant to other agents. In such cases, they are often administered in combination with other antimicrobial agents and with a loading dose preceding the standing dose.

^jOptimal efficacy against *P. aeruginosa* is obtained with intravenous continuous infusion.

β -lactam- β -lactamase inhibitor combination approved in July of 2019 for the treatment of complicated urinary tract infections and complicated intra-abdominal infections (Karlowsky et al., 2020; Lob et al., 2020; Smith et al., 2020). In November of 2019, cefiderocol gained its approval for the treatment of complicated UTI in adults with little to no other treatment options. It is the first antibiotic in its class of siderophore cephalosporins, with a broad spectrum of activity for Gram-negative bacteria. Cefiderocol binds to ferric iron and gains entrance into bacteria via ferric iron transporter systems, with subsequent destruction of cell wall synthesis (Morris and Cerceo, 2020; Wright et al., 2017).

Experts do not advise using quinolones other than ciprofloxacin or levofloxacin in the treatment of *Pseudomonas* infection (Kanj and Sexton, 2020). In addition, levofloxacin has no advantage over ciprofloxacin for *P. aeruginosa* therapy, since its additional spectrum of coverage is usually unnecessary. Fluoroquinolones are the only class of antibiotics available as an oral formulation that is reliably active against *P. aeruginosa*. For the oral route, ciprofloxacin should be dosed 750 mg every 12 h and levofloxacin 750 mg once daily.

All carbapenems given as single therapy have the propensity to induce resistance during treatment. However, meropenem and doripenem have lower propensity to develop resistance during therapy than imipenem (Kanj and Sexton, 2019d). For these reasons, some experts use carbapenems for the treatment of *P. aeruginosa* infections when the microorganism is resistant to other agents or in

polymicrobial infections (Kanj and Sexton, 2019d). In vitro studies have shown that the carbapenem minimum inhibitory concentration (MIC) is lowest with doripenem, followed by meropenem, then imipenem (Luyt et al., 2014). It is unknown whether this in vitro potency difference translates into any difference in clinical outcome (Kanj and Sexton, 2019d).

Treatment of serious *P. aeruginosa* infections focuses around the controversy of using monotherapy versus combination therapy (Kanj and Sexton, 2020; Paul and Leibovici, 2013). Combination therapy (either empirical or definitive) has been proposed for patients with known or suspected *P. aeruginosa* infection as a means to prevent the emergence of resistance, and to achieve a synergistic effect. Neither of these goals have been convincingly demonstrated to be achieved with combination therapy so far (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2020). However, combination therapy should be strongly considered in the severely ill patient for the empirical treatment of *P. aeruginosa* infections, especially in health care institutions with a high rate of resistant *Pseudomonas* (e.g., >10–15% to the chosen antibiotic class). Using combination therapy will thus ensure that at least one antimicrobial agent is effective against the infecting *P. aeruginosa* strain. De-escalation to a single antimicrobial agent, once antimicrobial susceptibility profiles are available, should then be undertaken (Bassetti et al., 2018; D'Agata, 2015; Falagas and Rafailidis, 2016; Kanj and Sexton, 2020). Aminoglycosides are a suboptimal treatment as monotherapy of *P. aeruginosa* infections; except for lower urinary tract infections or topical usage in other infections. Classically, a β -lactam as first agent and an aminoglycoside as the second have been used for combination therapy, provided there are no contraindications to its use. Addition of ciprofloxacin 400 mg every 8–12 h IV (instead of an aminoglycoside) has been suggested to fare equally well (Falagas and Rafailidis, 2016; Kanj and Sexton, 2020). When using an aminoglycoside as part of therapy, some experts favor tobramycin over gentamicin as it has greater intrinsic antipseudomonal activity (Kanj and Sexton, 2020). Other authorities, however, prefer amikacin when using aminoglycosides (Falagas and Rafailidis, 2020). Additionally, initiation of a second antipseudomonal agent may be reasonable in infections that are slow or fail to respond to a single agent, although there are few data to support this practice (Kanj and Sexton, 2020).

MDR in *P. aeruginosa* infections is a growing clinical problem. These infections should be managed with the assistance of an expert in the field (Kanj and Sexton, 2020). When *P. aeruginosa* is resistant to first line agents (including piperacillin, cephalosporins and carbapenems) the susceptibility to β -lactams-beta-lactamase inhibitors, such as ceftazidime-avibactam and ceftolozane-tazobactam should be checked (Hirsch et al., 2020; Kanj and Sexton, 2020). Antibiotics that have to be considered on a compassionate basis if resistance to other antipseudomonal agents is encountered include colistin (polymyxin E), polymyxin B and the parenteral formulation of fosfomycin sodium. These agents are used when no other options are available and typically associated to a second antibiotic, even if it only has partial activity (Kanj and Sexton, 2020). Care must be taken when dosing colistin, as formulations differ between the United States and European product, each having distinct dosing recommendations (Falagas and Rafailidis, 2020; Kanj and Sexton, 2020). One must also remember that ertapenem, ceftaroline, tigecycline, eravacycline, and plazomicin do not have antipseudomonal activity (Bassetti et al., 2018; Falagas and Rafailidis, 2020; Morris and Cerceo, 2020; Wright et al., 2017).

Finally, the control of the source of infection is of paramount importance when treating *Pseudomonas* infections. Adequate surgical control of the infectious foci (drainage, debridement) and/or removal of the infected foreign body (catheter, implant) is an essential measure in therapy (Falagas and Rafailidis, 2020; Kanj and Sexton, 2020).

Treatment of *Pseudomonas aeruginosa* bacteremia

In the management of *P. aeruginosa* bacteremia prompt active antimicrobial therapy is crucial, since delayed treatment is associated with a higher mortality rate (Falagas and Rafailidis, 2020; Kanj and Sexton, 2020). Therefore, combination therapy to ensure appropriate antibiotic coverage is advisable for empiric treatment of known or suspected *P. aeruginosa* bacteremia, especially in neutropenic patients (Martínez-Nadal et al., 2020). An extended-spectrum β -lactam and either an aminoglycoside or a fluoroquinolone may be used in combination therapy. De-escalation to the most appropriate single-agent therapy should be performed as soon as the susceptibility profile is known (Bassetti et al., 2018; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019c). Neither monotherapy with a quinolone (Falagas and Rafailidis, 2020) nor an aminoglycoside is suggested for the treatment of *P. aeruginosa* bacteremia, because they are associated with poor clinical outcomes (D'Agata, 2015; Falagas and Rafailidis, 2020; Kanj and Sexton, 2019c, 2020; Paul and Leibovici, 2013).

Another important consideration is the prolonged intravenous infusion of the antibiotic to exploit the pharmacokinetic/pharmacodynamic (PK/PD) properties of β -lactams in the treatment of *P. aeruginosa* (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019c; Valero et al., 2020). The therapeutic efficacy of β -lactam antibiotics depends on the time their blood concentration is above the MIC. Thus, with prolonged intravenous administration of β -lactams, their blood concentration is above the MIC for longer periods. There are data, mainly from nonrandomized studies and a relevant meta-analysis, that support the fact that prolonged infusion of piperacillin-tazobactam for 4 h may provide a survival benefit (Falagas and Rafailidis, 2016; Kanj and Sexton, 2019c). Meropenem is infused in a relatively short infusion of 30 min; an extended meropenem infusion is one that extends to 3 h.

Treatment duration is largely dictated by the primary site of the infection and the patient response. In nonneutropenic hosts, if the source of the bacteremia could be removed (e.g., an indwelling urinary catheter) and the patient has responded promptly to therapy, treatment can be stopped after 7–10 days (Kanj and Sexton, 2019c). In cases with undrainable foci of infection or slow clinical resolution, longer antimicrobial courses are necessary. In neutropenic patients, antimicrobial treatment should be continued at least 14 days or longer, until the absolute neutrophil count is equal to or greater than 500 cells/mm³ (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019c).

Treatment of pneumonia

Ventilator-associated tracheobronchitis may be difficult to distinguish from pneumonia and may progress to it. However, the 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS) do not recommend antibiotic therapy for ventilator-associated tracheobronchitis (Kalil et al., 2016). In these cases, a watchful and vigilant clinician's eye is necessary. In patients with nosocomial pneumonia, the IDSA and ATS guidelines recommend using clinical criteria alone to initiate antibiotic therapy rather than clinical criteria plus biomarkers (i.e., serum procalcitonin determination, PCR, or bronchoalveolar lavage fluid soluble triggering receptor expressed on myeloid cells [sTREM-1]); or clinical criteria plus the Modified Clinical Pulmonary Infection Score (Kalil et al., 2016).

Patients with nosocomial pneumonia may have *P. aeruginosa* isolates resistant to many antibiotics, a problem that appears to be progressively worse (Bassetti et al., 2018; Falagas and Rafailidis, 2020; Fernández-Cuenca et al., 2020; Kalil et al., 2016). In patients with suspected or known VAP, the 2016 Clinical Practice Guidelines by the IDSA and the ATS have recommended empirical treatment with an antipseudomonal β -lactam agent associated with a fluoroquinolone or an aminoglycoside if the patient has risk factors for MDR *Pseudomonas*, or >10% of the patient's isolates are resistant to the antibiotic chosen, or the patient is in an ICU where the local antimicrobial susceptibility is unknown. Patients with risk factors for MDR *Pseudomonas* isolates are those with prior intravenous antibiotic use within 90 days, septic shock at the time of VAP, acute respiratory distress syndrome preceding VAP, five or more days of hospitalization prior to the occurrence of VAP, and acute renal replacement therapy prior to VAP onset (Kalil et al., 2016). β -lactams based agents include piperacillin-tazobactam, ceftazidime, cefepime, imipenem, meropenem and aztreonam. In the setting of penicillin allergy, aztreonam can substitute the other β -lactams (Kanj and Sexton, 2019e). Moreover, in the absence of other options, it is acceptable to use aztreonam as an adjunctive agent with another β -lactam antimicrobial, because it has different targets on the bacterial cell wall (Kalil et al., 2016). Antibiotic dosages are shown in Table 3. These 2016 Guidelines suggest avoiding both aminoglycosides and colistin if alternative agents with adequate activity against *Pseudomonas* are available. Despite some reports indicating the opposite (Luyt et al., 2014), doripenem is not approved by the FDA to treat any type of pneumonia, based on a study comparing imipenem-cilastatin with doripenem in patients with pneumonia while on ventilators (FDA, 2019). The rationale to use combination therapy as empirical treatment of VAP is to ensure that at least one antimicrobial agent is active against *P. aeruginosa*. Once susceptibility profiles are available, monotherapy should also be considered because data supporting a higher efficacy of combination therapy are lacking (D'Agata, 2015; Falagas and Rafailidis, 2020; Kalil et al., 2016; Kanj and Sexton, 2019e). Patients with septic shock should also receive combination therapy (Kalil et al., 2016).

Aminoglycosides are not optimally active in the lungs at concentrations used for intravenous administration and are not recommended as monotherapy (D'Agata, 2015; Falagas and Rafailidis, 2020; Kalil et al., 2016; Kanj and Sexton, 2019e, 2020). However, the administration of aerosolized aminoglycosides may provide adequate drug levels in the tracheobronchial tree. The 2016 IDSA guidelines recommend inhalational therapy as an adjunct to systemic antibiotics in patients with nosocomial pneumonia in two situations: (i) patients with microorganisms that are susceptible only to aminoglycosides or polymyxins (colistin or polymyxin B); and (ii) as a last resort for patients who do not respond to intravenous antibiotics alone, regardless of the sensitivity of the microorganism (Kalil et al., 2016). Tobramycin (300 mg inhaled daily) and aztreonam lysine (75 mg inhaled three times daily for 28 days) have been shown to be safe and effective for patients with cystic fibrosis and have FDA approval only for these patients (Falagas and Rafailidis, 2020). Another antibiotic that has been used on a compassionate basis is the inhaled form of colistin. Inhaled colistin does not have FDA approval for patients without CF (Falagas and Rafailidis, 2020; Kanj and Sexton, 2019e).

The duration of antimicrobial treatment should depend upon the rate of improvement of clinical, radiological, and laboratory parameters. However, a 7-day course of antibiotics is the current recommendation by the IDSA and the ATS for patients with nosocomial *Pseudomonas* pneumonia (Kalil et al., 2016). Nonetheless, some experts advise for a course of 10–15 days or even longer, arguing that a shorter course may be suboptimal and associated with higher recurrence rates (D'Agata, 2015; Kanj and Sexton, 2019e). *P. aeruginosa* may continue to colonize the airway despite a clinical response; therefore, symptomatic improvement is a better indicator for antibiotic discontinuation (Kanj and Sexton, 2019e).

Treatment of other infections

The American Heart Association recommends cardiac surgery in combination with prolonged courses of combined antibiotic therapy in *P. aeruginosa* IE. Consultation with an expert in IE treatment should be sought. Combination antibiotic therapy with a β -lactam (penicillins, cephalosporins, or carbapenems) and either an aminoglycoside or fluoroquinolone for 6 weeks is reasonable (Baddour et al., 2015). If splenic abscess occurs as a complication of pseudomonal endocarditis, splenectomy should be performed prior to valve replacement (Kanj and Sexton, 2019c). In right-sided *Pseudomonas* IE, medical treatment is successful in 50–75% of cases (Baddour et al., 2015; Kanj and Sexton, 2019c). In the remaining patients, partial tricuspid valvectomy or "vegetectomy" without valve replacement is indicated. Placement of prosthetic valves should be avoided in these patients; because, typically, they have been IDU and have a high risk of recidivism (Baddour et al., 2015; D'Agata, 2015).

The majority of *P. aeruginosa* UTIs are complicated. Thus, the management of *P. aeruginosa* UTI involves antibiotic administration as well as correcting any obstruction and removing an indwelling catheter to prevent relapse (Falagas and Rafailidis, 2016; Kanj and Sexton, 2019a). Eradication of the organism is usually impossible in patients with *P. aeruginosa* UTI with a chronic indwelling bladder catheter (Kanj and Sexton, 2019a). Asymptomatic bacteriuria should not be treated, unless the patient is pregnant or is

undergoing an urologic procedure for which mucosal bleeding is expected (D'Agata, 2015; De Cueto et al., 2017; Nicolle et al., 2019). The duration of treatment for *P. aeruginosa* UTI is 3–5 days for cystitis; 7–10 days may suffice for pyelonephritis; although up to 2–3 weeks may be necessary for severe cases (Falagas and Rafailidis, 2016; Kanj and Sexton, 2019a). Fluoroquinolones (ciprofloxacin, levofloxacin) have the pharmacodynamic advantage of excellent concentrations in the urinary tract. Antipseudomonal β -lactam/ β -lactamase inhibitors and carbapenems also achieve high levels of urinary excretion (Falagas and Rafailidis, 2016).

The treatment of corneal infection usually consists of topical antipseudomonal formulations, containing aminoglycosides or fluoroquinolones (Kanj and Sexton, 2019a). In cases in which involvement is extensive, ceftazidime or gentamicin have been used via subconjunctival injection (Falagas and Rafailidis, 2016). Therapy for endophthalmitis includes vitrectomy and intravitreal antibiotics (Kanj and Sexton, 2019a). In addition, adjunctive systemic antibiotics are administered at high doses to achieve an adequate concentration in the eye. Ceftazidime and aminoglycosides are the antibiotics most frequently used in this entity (Falagas and Rafailidis, 2016).

Management of otitis externa involves the use of topical antibiotics, such as aminoglycoside-containing otic solutions (neomycin plus polymyxin B and hydrocortisone) and quinolone-containing otic solutions (ciprofloxacin 0.2% or ofloxacin 0.3%). Protection of the ear against moisture and avoidance of further mechanical injury by scratching are also important. For malignant external otitis, antipseudomonal antibiotics are the mainstay of treatment nowadays. Ciprofloxacin is the antibiotic of choice (D'Agata, 2015; Grandis and Yu, 2019). In cases of fluoroquinolone-resistant *P. aeruginosa*, other antibiotics should be used, such as piperacillin-tazobactam, ceftazidime, cefepime, or meropenem. In any case, a long treatment period of 6–8 weeks is necessary (D'Agata, 2015; Falagas and Rafailidis, 2016; Grandis and Yu, 2019). Therapy of malignant external otitis also involves surgical debridement of the ear canal, including any necrotic tissue cartilage and adjacent bone, rather than extensive bone debridement and facial decompression as was previously practiced (Falagas and Rafailidis, 2016; Grandis and Yu, 2019).

The IDSA 2013 guidelines for prosthetic joint infections caused by *P. aeruginosa* recommend treatment with cefepime, 2 g IV every 12 h, or meropenem, 1 g IV every 8 h, for 4–6 weeks. Alternative antibiotics to consider include ciprofloxacin, 750 mg orally twice a day or 400 mg IV every 12 h, or ceftazidime, 2 g IV every 8 h (Osmon et al., 2013). In these guidelines, the use of an aminoglycoside or two other active antibiotics could be considered. There are no recommendations for treatment of *Pseudomonas* arthritis or osteomyelitis (D'Agata, 2015). Therefore, the mentioned guidelines can be applied to the treatment of these infections. Ciprofloxacin has been used extensively in the treatment of chronic osteomyelitis due to *Pseudomonas* and the oral route may be an alternative to parenteral treatment (Falagas and Rafailidis, 2016). There are relatively few data regarding the appropriate duration of treatment. A duration of 6–12 weeks is most often reported (Falagas and Rafailidis, 2016).

In central nervous system infections, ceftazidime, cefepime or meropenem are preferred because of their good cerebrospinal fluid (CSF) penetration (Kanj and Sexton, 2019a; Tunkel et al., 2017). Alternative therapies are aztreonam and ciprofloxacin. Aminoglycosides may be added to these agents (Falagas and Rafailidis, 2016). The duration of treatment for meningitis extends to 10–21 days and repeat CSF cultures should confirm clearance of the microorganism (Kanj and Sexton, 2019a; Tunkel et al., 2017). Intra-ventricular antimicrobials are not approved by the FDA and specialists do not recommend their general use (Tunkel et al., 2017). In CSF shunt infections, removal of all components of the infected shunt, along with appropriate antimicrobial therapy appears to be the most effective treatment (Rodríguez-Lucas et al., 2020; Tunkel et al., 2017). Placement of a new shunt necessitates 10 days of sterile cerebrospinal culture (Tunkel et al., 2017). Brain abscess and epidural and subdural empyema generally require surgical drainage in addition to antibiotics (Falagas and Rafailidis, 2020).

Concluding remarks

Despite all the advances in medical care in recent years, infection due to *Pseudomonas* spp. continues to have an unacceptably high mortality rate, ranging from 30% to 60%. Furthermore, severe disabilities may be caused by *Pseudomonas* infection, such as loss of vision or impairment of neurological function. On the other hand, these infections are associated with increased length of hospitalizations and medical costs.

Antibiotic resistance in association with *Pseudomonas* infections is a growing clinical problem worldwide and will pose an enormous burden on human lives and financial resources in the near future. Once MDR *Pseudomonas* infection or carriage is detected in hospitalized patients, contact precautions should be implemented to prevent hospital spread. Factors that shorten the length of hospitalization and the judicious use of antibiotics are likely to decrease the incidence of this dreadful infection.

Introduction

Stenotrophomonas maltophilia, *Burkholderia cepacia* complex (Bcc) and other related microorganisms are a group of fastidious nonfermenters gram-negative bacillus. These environmental organisms can complicate treatment in those who are immunocompromised, critically ill in the intensive care unit and cystic fibrosis patients (CF).

Through a range of intrinsic antimicrobial resistance mechanisms, virulence factors, and the ability to survive in biofilms, these opportunistic pathogens are well suited to persist, both in the environment and the host.

Epidemiology and transmission

Stenotrophomonas, *Burkholderia*, and *Achromobacter* species are all ubiquitous environmental organisms found in water, soil, the rhizosphere, and in and on plants. All three organisms are capable of causing a variety of infections, including bacteremia, pneumonia, meningitis, urinary tract infections, and nosocomial infections from contaminated environmental sources (e.g., medications, nebulizers, dialysis fluids, saline solution, disinfectants, and contact lens fluid) (Brooke, 2012; Liu and Tong, 2019). A major virulence factor of these organisms is their ability to produce and survive with in biofilms (Tacconelli et al., 2014; Flores-Treviño et al., 2019).

Person-to-person transmission of these multidrug-resistant pathogens, especially among CF patients, remains a preoccupation. Unlike Bcc, where evidence for cross-transmission is well reported (Barchitta et al., 2009), less is known for *S. maltophilia*. However, case reports have documented incidences of patient cross-transmission (Diniz Rocha et al., 2020). The transmission of *S. maltophilia* to susceptible individuals may occur through direct contact with the source. The hands of health care personnel have been reported to transmit nosocomial infection in an intensive care unit.

S. maltophilia has been co-cultured with *P. aeruginosa* in respiratory samples obtained from CF patients. Cough generated aerosols from CF patients have the potential to provide airborne transmission of *S. maltophilia* (Wainwright et al., 2009).

The incidence of *S. maltophilia* hospital-acquired infections is increasing, particularly in the immunocompromised patient population. *S. maltophilia* infections can occur in both children and adults (Nayyar et al., 2017). The reported incidence of *S. maltophilia* infections seems to be increasing as the population of patients at risk increases. This increase is probably due to advances in the treatment of malignancy, increased use of invasive devices, and widespread use of broad-spectrum antibiotics.

S. maltophilia was among the 10 most common bacterial pathogens causing pneumonia in hospitalized patients from Europe, China, and the United States. The Bcc is a serious problem for cystic fibrosis patients and is increasingly occurring in hospital outbreaks in intensive care settings (Ramsay et al., 2013; Flamm et al., 2019).

Although *P. aeruginosa* and *S. aureus* continue to be the main colonizers in patients with CF, in recent years there has been an increase in the prevalence of *S. maltophilia* (4–15%) and *Achromobacter xylosoxidans* (3–8%) in these patients. Cases of colonization by two or more of these microorganisms have been described.

Microbiological and identification characteristics

S. maltophilia, formerly named *Pseudomonas* and then *Xanthomonas maltophilia*, is the only species in the genus. The name signifies “a unit feeding on few substrates,” based on the Greek roots *stenos* (narrow), *trophos* (one who feeds), and *monas* (a unit). *Maltophilia* means “affinity for malt,” based on the Greek roots *maltum* (malt) and *philia* (affinity). *S. maltophilia* bacteria are motile, free-living, glucose-non-fermentative, gram-negative aerobic bacilli with multitrichous polar flagella. *S. maltophilia* grows readily on most

bacteriologic media, typically appearing pale-yellow, grayish, or lavender-green when grown on blood agar. Preliminary identification may be facilitated by its ammonia-like odor. Most clinical isolates are oxidase negative and use maltose and usually dextrose and xylose. *S. maltophilia* may produce extracellular deoxyribonuclease on selected media, can hydrolyze esculin and orthonitrophenyl- β -D-galactopyranoside, and produces catalase and a strong acid reaction in oxidation-fermentation in maltose medium.

The *Burkholderia* genus, also originally of the genus *Pseudomonas*, contains more than 60 species and is found within the Betaproteobacteria class and Burkholderiales order. *B. cepacia* is referred to as a “complex” as it contains at least 17 genetically related species, formally designated as numbered genomovars. *B. cepacia*, now represents genomovar I of the large and diverse Bcc. Like *Stenotrophomonas* species, Bcc bacteria are motile, free-living, glucose-nonfermentative, gram-negative aerobic bacilli with multitrichous polar flagella. The appearance of Bcc colonies is variable, depending on the strain and the culture medium used. At present, MLST represents the most promising way for identifying species and strains of the Bcc.

Achromobacter and *Alcaligenes* species are gram-negative, motile, oxidase and catalase positive, non-fermenting rods. *Achromobacter xylosoxidans* was described in 1971 after being isolated from otic discharge samples from patients with chronic otitis media. The name stems from the ability of the organism to oxidize xylose readily, which is unique to the species. *A. xylosoxidans* was briefly renamed *Alcaligenes xylosoxidans*; however, it was placed back in the genus *Achromobacter* in 1998.

Modern laboratory identification techniques, such as matrix-assisted laser desorption ionization, time-of-flight mass spectrometry (MALDI-TOF MS) appears to identify and discriminate these organisms well.

On isolation, few biochemical reactions used to differentiate Bcc, *B. gladioli*, *Pandoraea* spp., *R. pickettii*, *A. xylosoxidans*, and *S. maltophilia* are enlisted in Table 1.

Mechanisms of resistance

S. maltophilia, Bcc and *A. xylosoxidans* have numerous intrinsic and acquired mechanisms of antibiotic resistance. Intrinsic β -lactamases, a wide range of efflux pump systems, enzymatic modifications, changes in the outer membrane and target site modification are just several of the mechanisms harbored by these organisms. Importantly, however, is the ability of these organisms to acquire new resistance determinants and to rapidly induce resistance. Intrinsic antibiotic resistance patterns in *S. maltophilia*, Bcc and *A. xylosoxidans* are important for physicians to consider when deciding on empiric therapy (Table 2).

Forms of clinical presentation

Stenotrophomonas, *Burkholderia* and *Achromobacter* species are capable of causing a variety of infections, including bacteremia, pneumonia, meningitis, urinary tract infections, and nosocomial infections from contaminated environmental sources (e.g., medications, nebulizers, dialysis fluids, saline solution, disinfectants, and contact lens fluid) have been reported (Abbott and Peleg, 2015). A major virulence factor of these organisms is their ability to produce and survive within biofilm.

The ability of *S. maltophilia* to form biofilm on various abiotic surfaces and tissues is an important feature of its virulence (Passerini de Rossi et al., n.d.). Biofilm consists of a community of bacterial cells that are attached to a surface and are embedded in an extracellular matrix composed of polysaccharides and proteins. This specific structure provides resistance to various antimicrobial drugs, antiseptic solutions and to the host immune defence. Biofilm formation contributes to the progression of CF lung disease and other chronic respiratory diseases (Pompilio et al., 2010). Biofilms were associated with 65% of the hospital-acquired infections, and *S. maltophilia* is a contaminant of a variety of medical devices and equipment (Brooke, 2012). Additionally, *S. maltophilia* can form biofilms on moist surfaces in direct or indirect contact with patients, such as respiratory tubing, catheters, intravenous lines, dialysis equipment, dental equipment and hospital plumbing systems (sinks and faucets) (Flores-Treviño et al., 2019).

S. maltophilia is not a highly virulent pathogen, but it has emerged as an important nosocomial pathogen associated with crude mortality rates is around 33% in children (Büyükcami et al., 2020; Alsuhaibani et al., 2021) and ranging from 16% to 60% in adults with bacteremia (Sumida et al., 2015; Bao et al., 2020; Hamdi et al., 2020).

Stenotrophomonas is increasingly recognized as an opportunistic pathogen responsible for nosocomial infections in intensive care unit patients (such as ventilator associated pneumonia and sepsis), life-threatening diseases in immunocompromised patients with hematological malignancies and cancers, and chronic pulmonary infections in patients CF (Nseir et al., 2006; Scholte et al., 2016).

The first challenge regarding management is to establish the clinical significance of culturing one of these nonfermenters from a clinical specimen. This question is largely irrelevant if these organisms are identified from sterile sites (e.g., cerebrospinal fluid, blood, and joint aspiration), but when they are identified either alone or with other organisms from nonsterile sites (e.g., sputum, wound swabs, and urine cultures), their role in disease may be difficult to ascertain. However, the repeated isolation of these organisms in the context of clinical disease or in unwell patients, antimicrobial therapy directed against these nonfermenters is often warranted.

The clinical manifestations of Bcc vary largely, ranging from no symptoms to severe respiratory infections and septicemia, especially in patients with cystic fibrosis or chronic granulomatous disease (Mahenthalingam et al., 2002). Uncommon presentations associated with Bcc were described in the literature, including but not limited to spontaneous bacterial peritonitis in

^aIntrinsic resistance patterns for *A. xylosoxidans* gathered from other reports in the literature.

From Abbott I and Peleg A (2015) *Stenotrophomonas*, *Achromobacter*, and Nonmelioid *Burkholderia* species: Antimicrobial resistance and therapeutic strategies. *Seminars in Respiratory and Critical Care Medicine* 36(1), 99–110. <https://doi.org/10.1055/s-0034-1396929>.

patients with liver cirrhosis, endophthalmitis post-ocular surgery and/or eye trauma, necrotizing fasciitis in an immunocompetent patient, genitourinary infections e.g., prostatic abscess in a child with chronic granulomatous disease, bladder wall abscess post-urethrocytostomy, and vaginitis in a patient with smoldering myeloma, skin and soft tissue infections with and without deep seated abscesses, especially in children with chronic granulomatous disease, etc. (Sfeir, 2018).

Treatment strategies

Reported rates of in vitro antibiotic resistance are very broad. The fact that these organisms are also frequently part of a mixed infection, especially when it comes to pulmonary involvement, adds to the complexity of management. In general, isolates from CF patients demonstrate higher rates of resistance than those found in other patient groups.

Stenotrophomonas maltophilia

There are many difficulties regarding the treatment of *S. maltophilia* infections, high level of intrinsic resistance against a large number of antimicrobial agents being the most significant one. It was reported that trimethoprim/sulfamethoxazole could be the treatment of choice. On the basis of in vitro pharmacodynamics modelling and the bacteriostatic action of trimethoprim-sulfamethoxazole, it is recommended that a higher dose be used (daily dose of 15 mg per kg of the trimethoprim component, split 6–8 h). Other approaches included treatment with a combination of antibiotics (trimethoprim/sulfamethoxazole and tigecycline, tigecycline and amikacin, aerosolized colistin and doxycycline), treatment by inhalation with aerosolized levofloxacin and tobramycin powder, and innovative treatments (nano-emulsions, phage therapy, plant oils) (Chang et al., 2015).

S. maltophilia is inherently resistant to carbapenems, and in fact, use of this class of antibiotic often selects for *S. maltophilia* in patients who are heavily immunosuppressed (e.g., neutropenic patients). The inclusion of a specific biofilm active agent, such as moxifloxacin or levofloxacin has also been shown to be of benefit (Di Bonaventura et al., 2004; Wu et al., 2013) although caution should be applied when used as monotherapy because of the risk of rapid induction of resistance. Minocycline and tigecycline have also shown some promise to assist with the treatment of *S. maltophilia* (Farrell et al., 2010; Church et al., 2013). Recent studies revealed that *S. maltophilia* was highly susceptible to cefiderocol (MIC₉₀ 0.5 mg/L) and cefiderocol was at least as active as comparators, including trimethoprim/sulfamethoxazole (MIC₉₀ 2 mg/L) (Delgado-Valverde et al., 2020). The evidence for combination therapy often comes from in vitro synergy testing data, and highlights the need for further research into optimal therapy for this troublesome organism. The combinations are often reported involving trimethoprim-sulfamethoxazole, ticarcillin-clavulanate, moxifloxacin, levofloxacin, aztreonam, ceftazidime, colistin, rifampicin, tigecycline, and minocycline (Falagas et al., 2008; Milne and Gould, 2012; Church et al., 2013).

Burkholderia cepacia complex

Trimethoprim-sulfamethoxazole remains a recommended first-line therapy. Combination therapy is often used for patients who are more severely unwell, and includes double and triple combinations of first and second line agents. In contrast to *S. maltophilia*, Bcc are often sensitive to meropenem, which is another first-line therapy, but are inherently resistant to polymyxin and colistin. Tigecycline demonstrates poor activity against Bcc owing to drug efflux, although minocycline maintains activity.

The role of penicillins, namely, piperacillin-tazobactam and ticarcillin-clavulanate remains controversial given the different intrinsic resistance reports between EUCAST and CLSI. Inhaled tobramycin has the potential to achieve high pulmonary concentrations to inhibit Bcc isolates, despite widespread resistance reported (Trapnell et al., 2012).

Achromobacter xylosoxidans

Less is known about the optimal therapy for *Achromobacter* spp. In addition to the recognized intrinsic antibiotic resistance patterns, acquired resistance is also widely reported.

The most active agents are piperacillin-tazobactam, meropenem, and trimethoprim sulfamethoxazole, whereas ceftazidime is more active than cefepime (Almuzara et al., 2010; Atalay et al., 2012; Wang et al., 2013). Tetracyclines (e.g., minocycline) have variable activity and may be vulnerable to a multidrug efflux pump (Bador et al., 2013).

Aminoglycosides, fluoroquinolones, fosfomycin, and aztreonam all have poor activity. Multidrug-resistant phenotypes and carbapenemase-producing isolates have been reported, especially for the CF patient population, further complicating therapeutic options (Bador et al., 2013). Combination therapy has been recommended for the treatment of *A. xylosoxidans* pulmonary exacerbations in CF. Although the use of concurrent inhaled antibiotics, such as inhaled colistin, could also be considered.

Introduction

The non-fermentative Gram-negative bacilli such a *Moraxella* spp. and other genus that will discuss in the chapter, are a group of aerobic, non-spore-forming bacilli, that do not use carbohydrates as a source of energy or degrade them in another way than fermentation. Over the past 3 decades, *Moraxella* (*Branhamella*) *catarrhalis* has emerged as an important and common human respiratory tract pathogen. This bacterium was transferred to a new genus named *Branhamella* on the basis of differences in fatty-acid content and DNA hybridization studies compared with other *Neisseriaceae* (Rossau et al., 1991). At this time, *Moraxella catarrhalis* is the most widely accepted name. The genus *Moraxella* comprises more than 20 species that are part of the normal microbiota of the human respiratory tract. *Moraxella* species are coccoid or coccobacillary microorganisms appearing usually in pairs and sometimes in short chains, tending to resist decolorization in the Gram stain. *M. catarrhalis* and *M. canis* are *Neisseria*-like diplococcic.

In this chapter, we have summarizes the main characteristics of the genus *Moraxella* and we have also included other non-fermentative Gram-negative bacilli such as *Oligella* and *Elizabethkingia* species which recently have demonstrated to be pathogens in the human population.

Moraxella (Branhamella) catarrhalis

Throughout history, *Moraxella catarrhalis*, has several taxonomic changes. It was initially named as *Micrococcus catarrhalis*, later it was renamed as *Neisseria catarrhalis*, owing to they share a similar morphology, phenotype and ecological niche with *Neisseria* species. Seeing the limited DNA homology with these species, it was described a new genus, *Branhamella*. Then, it was suggested that *Branhamella catarrhalis* was close to others species of *Moraxella* spp. There is no evidence to separate *B. catarrhalis* from *Moraxella* genus, so it should be included in this genus. Actually, *Moraxella* genus englobe cocci and short bacilli genetically related. Some authors prefer the name of *B. catarrhalis* because of other *Moraxella* species are short bacilli while *M. catarrhalis* (Rossau et al., 1991; Enright and McKenzie, 1997).

M. catarrhalis it is accepted as the third most important pathogen in the human respiratory tract, although until recently it was considered as a normal flora of the upper respiratory tract. Since it was recognized as a possible pathogen it was further investigated.

Epidemiology

It is believed that the only natural habitat is exclusively human. *M. catarrhalis* and other species of medical importance as *M. lacunata*, *M. osloensis*, *M. atlantae*, *M. nonliquefaciens*, can be found on nasopharynx and throat and other parts of the upper respiratory tract. They can also be found in conjunctiva and some species, like *M. osloensis*, in urogenital tract (Naheed et al., 2003; Forbes et al., 2002). Unlike *M. catarrhalis*, most of them are rarely associated with infections and are considered opportunistic. *M. catarrhalis* is the most frequently causes disease in humans.

M. catarrhalis is capable of colonizing without causing disease. The percentage of colonization depends on several factors. Age is one of them. The percentage of colonization in infants and children is high (up to 75%) while in healthy adults is very low (about 1–5%). There is not a clear reason for the difference in the carriage rates. One possibility could be the age-dependent production of the secretory immunoglobulin A (IgA). However, IgG antibody levels are not correlate with the percentage of colonization (Murphy, 1998; Verduin et al., 2002). According to the season, different levels of colonization have also been found, being higher during autumn and winter than in spring and summer (Van Hare et al., 1987). Some studies performed with respiratory samples from patients with chronic respiratory diseases have analyzed and described that some adults with chronic lung diseases appear to have a higher colonization rate than those who are healthy (Murphy, 1998). Some authors have described a relationship between geographical or socio-economic situation and colonization. A lower purchasing power has been associated with a higher possibility of overcrowding and less hygiene, which contributes to a higher possibility of colonization (Karalus and Campagnari, 2000).

Microbiology

Members of genus *Moraxella* are aerobic non-fermentative Gram-negative bacilli. In Gram stain they are tiny and look like bacilli or elongated diplococci. All of them are non-motile.

Colonies of *M. catarrhalis* grow well on both blood and chocolate agars. Generally, colonies on blood agar are non-hemolytic, round, gray to white, smooth, convex, opaque, and after 24 h of incubation they measure about 1–3 mm. Those colonies can be move and remain intact on the agar surface, like a “hokey puck” (Schreckenberger et al., 2007).

M. catarrhalis is catalase positive and strongly oxidase positive, but other tests are needed to identify it. Tests can be done on the strains to confirm the production of DNase and reduction of nitrate and nitrite. They do not produce acid from glucose, maltose, sucrose, lactose, and fructose but they have ability to hydrolyze glycerol tributyrat (Catlin, 1990).

In addition to *M. catarrhalis*, another species frequently isolated in human specimens is *M. nonliquefaciens*. These isolates are semiopaque and smaller (0.1–0.5 mm) than *M. catarrhalis* and some of them can pit the agar. Colonies of *M. osloensis* are similar but pitting is not common. *M. lacunata* y *M. atlantae* have small colonies and pitting is common. Growth of *M. atlantae*, *M. nonliquefaciens* and *M. lacuna* are similar in many of their features but, for example, growth of *M. atlantae* is stimulated by bile salts and sodium deoxycholate, while *M. nonliquefaciens* and *M. lacunata* are not (Schreckenberger et al., 2007).

Pathogenicity

The increasing importance that *M. catarrhalis* has acquired has increased the study of this bacterium. Research has promoted the study of virulence factors involved in the pathogenesis of infection and its immunogenicity. Several bacterial factors have been identified as contributing of virulence. Depending on the factor, it will be present in some or all isolates. Some of these factors have been considered as potential vaccine candidates.

Lipopolysaccharide

Lipopolysaccharide (LPS) or lipooligosaccharide (LOS) is a glycolipid exposed on the surface of the outer membrane. Unlike enteric Gram-negative bacteria it consists only of lipid A and an oligosaccharide part, that lacks O-antigen side chain. It appears to be more antigenically conserved and it is similar to other gram-negative bacteria like *Haemophilus influenzae* (Holme et al., 1999). The lipid A part is similar to that other bacteria. Although *M. catarrhalis* do not require LPS to be viability, it is an important virulence factor and it is involved in adherence and invasion epithelial cells and serum resistance (de Vries et al., 2009; Blakeway et al., 2017).

Three serotypes have been described: A, B and C. Serotype A is the predominant one (60%) while B (30%) and C (5%) represent a smaller number. Serotypes A, B and C represent 95% of the strains while 5% are unidentified. They have common epitopes that cause cross reactions between serotypes but also with other bacteria (Holme et al., 1999; de Vries et al., 2009).

Peptidoglycan

M. catarrhalis has multiple layers of peptidoglycan. That peptidoglycan triggers an efficient macrophage response, inducing the secretion of NO/NO₂ and TNF- α -independent tumoricidal activity (Keller et al., 1992).

Outer membrane proteins

Outer membrane proteins (OMPs) have been classified based on its electrophoretic mobility using sucrose gradient purification and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Eight types were identified (A-H). In addition to OMPs A to H, a new OMPs has been described, which will be developed below.

- Ubiquitous surface protein A (UspA)

The UspA family consists of UspA1 and UspA2, which are structurally related. Different functions are attributed to this family of proteins. Although they are structurally related, they are involved in different biological functions. UspA1 having been shown that is mainly involved in adherence and attachment to epithelial cells and biofilm formation. However, UspA2 is essential for complement evasion and serum resistance (Aebi et al., 1998; Verduin et al., 2002; de Vries et al., 2009; Blakeway et al., 2017).

- Outer membrane protein CD (OMP CD)

It has been shown that the initially called OMPs C and D are two stable forms of the same protein, the OMP CD. This protein is heat-modifiable and it is highly conserved among strains, which produce an immunogenic response. It has been seen that it is involved in adherence to epithelial cells and mucin from nasopharynx and middle ear, therefore, it is a way of promoting the invasion of the bacteria (Holm et al., 2004; Blakeway et al., 2017).

- Outer membrane protein E (OMP E)

OMP E is a heat-modifiable protein that is abundantly expressed in the bacterial surface and is highly conserved among strains, but it appears not to be very immunogenic (Blakeway et al., 2017). It has been described its implication in the acquisition of nutrients as well as serum resistance (Murphy et al., 2000; Verduin et al., 2002; de Vries et al., 2009; Blakeway et al., 2017).

- Outer membrane protein B2 (OMP B2) or CopB

This protein is present and is fairly well conserved in most of strains. It seems to be involved in iron acquisition and serum resistance (Verduin et al., 2002; de Vries et al., 2009; Blakeway et al., 2017).

- Hemagglutinin/Moraxella IgD binding protein (Hag/MID)

This protein, designated Hag (hemagglutinin) is also known as MID, is expressed by most strains of *M. catarrhalis*. It is involved in hemagglutination, autoagglutination and adherence to respiratory human cells (Murphy et al., 2019) and also biofilm formation (de Vries et al., 2009), which it leads to colonization of the host.

Fimbriae

Fimbriae, also called pilus, are spread along the bacterial surface. Type IV pilus (T4P or TFP) are polymers of the major pilin protein that are present in most of strains. It is associated with bacterial adherence to the host epithelial cells that plays an essential role in colonization (Luke et al., 2007; de Vries et al., 2009).

Biofilm formation

It is known that biofilm formation is important for persistence and colonization. Biofilm formation capacity of *M. catarrhalis* is already demonstrated by in vitro assays, and it is shown that play a role in chronic middle ear infections. Self-produced matrix that adheres to a surface makes relatively resistant to antibiotics and action of the immune system (Pearson et al., 2006; de Vries et al., 2009).

Other virulence factors

- *M. catarrhalis* adherence protein (McaP)

It was classified as a conventional autotransporter. It is highly conserved OMP in most of *M. catarrhalis* strains. McaP may be involved in adhesion, playing an important role in colonization. It also may display the enzymatic activity of an esterase and phospholipase, involved in a diverse range of cellular functions (Lipski et al., 2007; de Vries et al., 2009).

- Filamentous Hemagglutinin-Like Proteins (FHA-like proteins)

FHA-like proteins were shown to function as a two-partner secretion locus (TPS), involved in adherence to epithelial cells. These proteins were designated as MhaC (transporter), MhaB1 (exoprotein), and MhaB2 (exoprotein). TPS are present in other Gram-negative bacteria. They are found on the outer membrane and directly mediate attachment to human epithelial cells (Lipski et al., 2007; Plamondon et al., 2007).

- Toll-like receptor (TLRs) activation

TLRs are important components of the innate immune system that recognize pathogen. TLRs are involved in defense of the airways. *M. catarrhalis* induces an inflammatory response upon contact with TLR2 in respiratory airways, starting a cascade of reactions and having an important role in COPD exacerbation (de Vries et al., 2009; Perez Vidakovics and Riesbeck, 2009).

Complement resistance

Colonization means survival; therefore, it is necessary to interfere with the different components of the immune system. Complement system is the first line of innate defense against pathogenic microorganisms. Activation of the complement system triggers a protein cascade. Deposition of complement proteins on the bacterial surface provokes attack and opsonization of bacteria and its phagocytosis.

LOS structures are involved in serum resistance. Modifications in its structure have an impact on the response to the complement, making it more susceptible to it.

In addition to LOS, OMPs are also involved in complement resistance. UspA proteins play an important role in serum resistance. Both UspA1 and UspA2, are involved, but UspA2 affinity to complement proteins is higher than that of UspA1. It influences both in the classical and the alternative pathways. It is capable of binding to C4b binding protein (C4BP), C3 and vitronectin. C4BP is a regulator of the classical pathway of complement system. The binding of the α -chain of C4BP to the bacterial surface inhibits the classical pathway. Union also occurs with C3. UspA proteins bound to C3d fragment of C3 and inhibit the alternative pathway, increasing its survival. Also binds with vitronectin, which is involved in the regulation of the terminal pathway of complement system. It recruits vitronectin which allows to regulate the membrane attack complex (MAC) formation. Other OMPs like OMP CD, OMP E and CopB are also involved in complement resistance. Mutants without those proteins are more susceptible to the complement action (de Vries et al., 2009; Riesbeck, 2020).

Clinical manifestations

Otitis media

Otitis media (OM) is an inflammation of the middle ear. *M. catarrhalis* was recognized as a presumable OM pathogen in the 1980s and since then the reported cases have been increasing, particularly in children. Approximately 80% of children have had an episode of acute otitis media (OMA) in the first 3 years of their life. It is one of the most common reasons for medical consultation and prescription of antibiotics in children (Murphy and Parameswaran, 2009). Therefore, OMA has an important impact on the health of children.

Culture of the middle ear fluid (MEF) obtained by tympanocentesis is the standard for etiological diagnosis (Verduin et al., 2002; Murphy and Parameswaran, 2009; Sillanpää et al., 2016). The most common bacteria we found causing OMA are *Streptococcus pneumoniae*, non-typeable *Haemophilus influenzae* and *M. catarrhalis*. Around 15 to 20% of cases of OMA isolated from MEF are caused by *M. catarrhalis* (Murphy and Parameswaran, 2009). OMA caused by *M. catarrhalis* is clinically milder and less virulent than that caused by *S. pneumoniae* (Palmu et al., 2004; Murphy and Parameswaran, 2009).

There is an association between nasopharyngeal colonization and OMA. Nasopharyngeal carriage of the OMA major pathogens may carry an increased risk of OMA (Faden et al., 1991). It is relatively frequent that after a viral infection of nasopharynx an OMA appears. This is because the middle ear mucociliary clearance is less effective than in a normal situation, owing to the bacteria will stay longer in fluid ear and multiply, causing OMA (Owen, 2002).

Clinical manifestations of OMA include acute onset of otalgia, presence of MEF or inflammation with or without other nonspecific symptoms such as fever, rhinitis or vomiting. In bacterial OMA is characteristic of the bulging tympanic membrane that has purulent fluid. This is the best predictor of OMA, but is not always present (Lieberthal et al., 2013; Ngo et al., 2016). Tympanocentesis and culture is not always possible and it is not done routinely. This is because in most cases diagnosis is established using signs and symptoms. These characteristics do not allow differentiating the etiologic agent so generally OMA is empirically treated (Verduin et al., 2002; Murphy and Parameswaran, 2009).

M. catarrhalis can also produce recurrent otitis media (ROM) and otitis media with effusion (OME). OME is the presence of MEF without clinical signs of OMA. Children who have at least 3 episodes of OMA in 6 months or at least 4 episodes of OMA in 12 months or at least 8 months with MEF in a year are prone to recurrent otitis. Biofilm formation has been correlated with ROM and OME. This makes it more resistant to the antibiotic and immune system action (Murphy and Parameswaran, 2009; Ngo et al., 2016).

OME is more common than OMA. OME can be accompanied of a viral nasopharyngeal infection and be predictive of a future OMA.

Sinusitis

Most sinus infections are of viral origin. Sinusitis generally develops after an episode of viral upper respiratory infection and only a small number of patients may develop acute or subacute purulent sinusitis. Other predisposing event but in a lower percentage, is allergic inflammation. Sinus are connected with the nasal cavity, so the microbiology of sinusitis is related with that resides in the nasopharynx. As in otitis media, sinusitis is a very common disease in childhood and is most common after a viral upper respiratory infection. *M. catarrhalis* is the third most common cause of acute sinusitis in adults and children after *S. pneumoniae* and non-typeable *H. influenzae*. *M. catarrhalis* produce 20% of cases in children, but in adults is a smaller portion (Verduin et al., 2002; Murphy and Parameswaran, 2009). Sinus aspiration and culture determinate the etiological agent but is not performed routinely. In addition, infection is underdiagnosed because its symptoms are nonspecific.

Lower respiratory tract infections

The most common bacterial causes of respiratory infections are *S. pneumoniae*, non-typeable *H. influenzae* and *M. catarrhalis*.

M. catarrhalis is not a common pathogen causing a lower respiratory tract infection in healthy persons. Healthy people respiratory tract is sterile beyond the vocal cords, but in some cases, patients with predisposing factors can develop a pulmonary infection caused by *M. catarrhalis*.

This pathogen can produce respiratory infection in persons with chronic obstructive pulmonary disease, person with various forms of immunosuppression or pneumonia in elderly and can play a role as nosocomial respiratory tract pathogen.

- Lower respiratory tract infections in chronic obstructive pulmonary disease (COPD)

COPD is one of the most common causes of deaths in the world, causing a high mortality, morbidity and health care cost. COPD exacerbation is sustained worsening of a patient's condition. It is known that a lot of exacerbation is caused by bacterial infection, without forgetting those produced by viruses or non-infectious causes. These periods of increased airway inflammation may accelerate the progressive loss of pulmonary function in these patients.

M. catarrhalis and non-typeable *H. influenzae* strains are the most common bacterial pathogens causing acute exacerbations and chronic lower respiratory airway infection in COPD (Murphy et al., 2019).

The possible implication of *M. catarrhalis* in exacerbation of COPD has been ignored during decades. In patients with COPD, lower respiratory tract is colonized by bacteria, including *M. catarrhalis*, as a result of deficient mucociliary clearance. Around 5 to 35% of patients appear to be chronically colonized by *M. catarrhalis* and sometimes with different strains (Murphy et al., 2005). The acquisition of a new strain may play a role in episodes of exacerbation, thus triggering an immune response and its corresponding airway inflammation. During these episodes is seen an elevation of inflammation markers compared with no bacterial exacerbation.

The clinical presentation of *M. catarrhalis* during COPD exacerbation is similar to those due to another pathogen as *S. pneumoniae* or not-typeable *H. influenzae* (Verduin et al., 2002). The typical clinical presentation is an increased sputum production, increased sputum purulence and increased dyspnea. Other variability symptoms are fever and fatigue. Pleuritic pain, empyema and bacteremia are uncommon. Examination of the chest show ronus and generally decreased air entry with localized crackles. If patient has a coinfection with other low respiratory tract pathogens, infection may be more severe.

Gram stain smear of sputum or other lower respiratory tract samples reveals polymorphonuclears and abundant gram-negative elongated bacilli.

- Pneumonia in the elderly

Pneumonia due to *M. catarrhalis* does not occur frequently but it causes an important portion of pneumonia in elderly persons (older than 65 years). Most elderly patients who present community-acquire pneumonia have underlying cardiopulmonary disease including COPD, diabetes or are smoker or ex-smoker. About 10% of pneumonia cases in the elderly are caused by *M. catarrhalis* (Murphy, 2005). Seasonal variation may play a role in the ability to cause disease of *M. catarrhalis*, being more common in autumn and winter months.

- Nosocomial respiratory tract infection

Nosocomial transmission has been observed in some units in hospital environment. There is evidence of spread of *M. catarrhalis* within health care environment (McGregor et al., 1998; Verduin et al., 2002). Analysis of some isolates indicates that some cases were caused by the same strain, confirming person-to-person transmission.

Ocular infections

Infections of the eye can be caused by different microorganisms. Conjunctivitis is a frequent infection and it is more remarkable in pediatric population. *M. catarrhalis* is a frequent cause of acute conjunctivitis in children along with *H. influenzae* and *S. pneumoniae*. These episodes of conjunctivitis are commonly associated with upper respiratory infections but also can be transmitted directly from infected persons or for proliferation of normal flora. Blepharitis, that can be associated with conjunctivitis, can also be caused by *M. catarrhalis* among other microorganisms. Blepharitis is an inflammatory process involving the eyelids. *M. catarrhalis* can be isolated from swab or scraping culture. However, the isolation of these organisms may be carefully interpreted because it is part of the normal flora. Hence, is desirable collect sample in parallel from both eyes (healthy and infected) (Azari and Barney, 2013; Díaz López et al., 2019).

M. catarrhalis can also produce keratitis which affect cornea, and may progress to endophthalmitis (Berrocal et al., 2001).

Bacteremia

Bacteremia is an infrequent manifestation of *M. catarrhalis* infection. It has been described in patients with a wide range of age. Most of cases were associated with a respiratory focus or have some underlying pathology (Verduin et al., 2002; Murphy and Parameswaran, 2009).

Other Moraxella species infections

Other *Moraxella* species are unusual pathogens in humans. It has to be emphasized that other *Moraxella* species are frequently associated as an ocular pathogen. *M. lacunata* has been typically associated with eye infections. Moreover, *M. lacunata* is more common in chronic than acute conjunctivitis. Other species like *M. nonliquefaciens* and *M. osloensis* are also involucrate in these infections. Thus, *Moraxella* species can also cause conjunctivitis, keratitis and rarely endophthalmitis (Murphy, 2005).

Some case reports published in the medical literature have shown that these species can be as unusual cause of invasive infection in human, including endocarditis, septic arthritis, purulent pericarditis, cellulitis and meningitis. Patients experiencing meningitis due to *Moraxella* species are characterized by a high frequency of inherited and acquired complement deficiencies (Murphy, 2005).

Microbiological diagnosis

Colony morphology can change depending on the culture medium used and it is difficult to differentiate between *Moraxella* species.

Identification using biochemical has been traditionally used to identify these bacteria. The most used criteria for its identification are the following:

- Absence of pigmentation in blood agar (non-hemolytic).
- Production of oxidase and catalase.
- Production of DNase.
- Hydrolysis of tributyrin.
- Absence of acid production from glucose, maltose, sucrose and fructose.
- Reduction of nitrates and nitrites.

Biochemical tests have poor resolution to differentiate between some species because most *Moraxella* species have similar biochemical responses. The introduction of the matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has allowed to the microbiology laboratory's ability to differentiate *Moraxella* species (Takahashi et al., 2019). This method is relatively rapid and accurate in comparison with biochemical identification.

Serodiagnostic techniques are not generally used for the laboratory diagnosis of infection caused by *Moraxella* species.

New DNA-based technologies have opened new possibilities for detection of *M. catarrhalis* and other *Moraxella* species in clinical samples without needing bacteriological culture. Polymerase chain reaction (PCR) based analyses have been tested for direct detection of *M. catarrhalis* DNA. There are several limitations of conventional culture methods to detect etiological agents involved in middle ear infections (Post et al., 1995). PCR has been used to improve the sensitivity and specificity of bacterial detection in middle ear effusion. 16S rRNA gen was targeted, which is found in multiple copies (Hendolin et al., 2000). It has been described multiplex PCR to detect main pathogens involved in these infections.

Treatment

Before 1970s, almost all isolates of *M. catarrhalis* were described as susceptible to penicillins (McGregor et al., 1998; Murphy, 2005). Therefore, these antibiotics were considered an adequate treatment for *M. catarrhalis*. But at the end of 1970s, first cases of beta-lactamase-producing strains were described. Now, more than 90% of *M. catarrhalis* strains produce beta-lactamase. This dramatic rise could be influenced by the increased prescription of beta-lactam antibiotics. If beta-lactamase production is demonstrated it should be assumed that hydrolyze penicillin, ampicillin and amoxicillin, but not all beta-lactams antibiotics are inactivated by these enzymes. It remains susceptible to cephalosporins (McGregor et al., 1998). Therefore, empiric use of penicillin or amoxicillin cannot be recommended (Wallace Jr et al., 1990). Beta-lactamase enzyme can be inactivated by beta-lactams inhibitors so it can be used amoxicillin in combination with clavulanic acid. The beta-lactamase stable cephalosporins or amoxicillin-clavulanic acid are generally the drugs of choice.

Antimicrobial susceptibility testing is generally recommended, although *M. catarrhalis* remains susceptible to a wide number of antibiotics such as trimethoprim-sulfamethoxazole, tetracyclines, oral cephalosporins, macrolides, fluoroquinolones and aminoglycosides (Murphy, 2005).

All isolates of *M. catarrhalis* are intrinsically resistant to trimethoprim, vancomycin and clindamycin (McGregor et al., 1998).

Treatment of the most common infectious diseases caused by *M. catarrhalis* is generally empirical. Thus, the chosen treatment is usually active against the pathogens that most commonly cause these infections (*S. pneumoniae*, *H. influenzae* and *M. catarrhalis*).

- Beta-Lactamase Production

The first beta-lactamase-producing strain was described in 1976. This beta-lactamase was called BRO (BRanhamella mOraxella). Two related beta-lactamase, BRO-1 (previously Ravasio-type enzyme) and BRO-2 (previously 1908-type enzyme) have been described. At the end of the decade of the 1990s, the percentage of this type of strains was more than 90%, but these percentages remain until today (McGregor et al., 1998; Bootsma et al., 2000). Genes of both BRO-1 (*bro1*) and BRO-2 (*bro2*) are located at the same chromosomal locus. Both alleles differ only in 5 bases and by only a single amino acid. The majority beta-lactamase produced by *M. catarrhalis* strain is BRO-1 and express higher levels of ampicillin resistance than those produced by BRO-2. Differences in the promoter region have been observed, that may explain this different expression (Bootsma et al., 2000).

It has been demonstrated that other *Moraxella* species produce similar beta-lactamase enzymes. *M. nonliquefaciens* and *M. lacunata* produce BRO-1 and BRO-2. *M. osloensis* produce beta-lactamase but is different to BRO-1 and BRO-2. Another beta-lactamase with a different hydrolysis pattern have described too. It seems to be a predominant beta-lactamase enzyme produced by other *Moraxella* and *Oligella* species (Wallace Jr et al., 1989).

Oligella species

The genus *Oligella* is composed of two species: *O. ureolytica* and *O. urethralis*. *O. ureolytica* was assigned by CDC (Center for Disease Control) to group IVe and *O. urethralis* to CDC group M-4 and formerly *Moraxella urethralis*. In 1970 the analysis of the DNA of both species, allowed to create the genus *Oligella* (Lautrop et al., 1970; Rossau et al., 1987).

Epidemiology

Both species are present as a normal flora in the human genitourinary tract and most isolates were described from human urine (Koneman, 2006; Steinberg and del Rio, 2005). *Oligella* species have been described in respiratory samples, so that indicates that it could colonize the human respiratory tract (Fernández-Olmos et al., 2012).

Microbiology

Oligella species are small and non-capsulated Gram-negative bacilli. Moreover, its name, *Oligella*, refers to its small size. Both species are catalase and oxidase positive, do not ferment or oxidize carbohydrates, do not produce hydrogen sulfide, indole and do not hydrolyze esculin and gelatin. Most strains can grow on MacConkey agar, being visible small non-lactose fermenting colonies after 2–4 days (Baqi and Mazzulli, 1996).

O. urethralis is similar to *Moraxella* species. Colonies, when grow on blood agar, are non-hemolytic, convex, and semiopaque to whitish. Colonies of *O. urethralis* are smaller than those of *M. osloensis*. Colonies of *O. ureolytica* have a relatively slow growth. It is found very small punctate colonies after 24 h of incubation on blood agar medium. After 3 days of incubation, it is found non-hemolytic, white, opaque and large colonies (Koneman, 2006; Schreckenberger et al., 2007).

The main differences between both species are that *O. urethralis* non-motile, does not produce urease and cannot reduce nitrate to nitrite. However, *O. ureolytica* is motile because it has peritrichous flagella, produce urease and can reduce nitrate to nitrite (Schreckenberger et al., 2007).

Pathogenicity

Both *Oligella* species are considered opportunistic pathogens and their role in pathogenicity is low or uncertain. Generally, infection chiefly occurs in persons with underlying conditions (Beauruelle et al., 2019).

Clinical manifestations

Infections due to *Oligella* species are rare but some cases have been described, mainly in patients with underlying predisposing factors.

These bacteria have mainly been found causing urinary infection, including urosepsis. Some cases of bacteremia produced by these species have also been described (Pagotto et al., 2016). Even less frequent are infections with extragenitourinary location, but cases of septic arthritis or lymph node infection have been described (Mesnard et al., 1992; Baqi and Mazzulli, 1996). Patients with cystic fibrosis or chronic obstructive pulmonary disease have also been reported (Beauruelle et al., 2019).

Microbiological diagnosis

A presumptive identification can be performed using Gram stain, colony morphology and some biochemical characteristic such as positive catalase and oxidase reactions. Final identification using biochemical tests is unreliable in laboratory practice routine. Misidentification of these two pathogens may be involved in the few cases of infections have been described. The introduction of

techniques such as MALDI-TOF MS or molecular techniques facilitates the identification of these microorganisms (Branda et al., 2014; Almuzara et al., 2015; Fernández-Olmos et al., 2012).

Treatment

O. urethralis is susceptible to most antibiotic, including penicillins, cephalosporins, aminoglycosides, chloramphenicol, erythromycin, tetracycline and trimethoprim sulfamethoxazole (Pagotto et al., 2016; Beauruelle et al., 2019). It has been reported several cases of fluoroquinolones resistance therefore empiric treatment with these antibiotics may not be recommended (Pugliese et al., 1993; Riley et al., 1996).

Most strains of *O. ureolytica* are susceptible to aminoglycosides, cephalosporins and colistin but using usual achievable serum concentrations it has been described resistance to penicillin, ampicillin, erythromycin, tetracycline, chloramphenicol and trimethoprim sulfamethoxazole (Welch et al., 1983; Koneman, 2006).

There are some beta-lactamase-producing strains which are resistant to penicillin and ampicillin (Welch et al., 1983; Pugliese et al., 1993). These bacteria are capable of acquiring resistance mechanisms. It has been described a chromosomal integration of a cephalosporinase gene from *Acinetobacter baumannii* into *O. urethralis* (Mammeri et al., 2003).

Elizabethkingia spp.

Currently, six species belong to the genus *Elizabethkingia*, namely, *E. meningoseptica*, *E. miricola*, *E. anophelis*, *E. ursingii*, *E. bruuniana*, *E. occulta*.

It was first described in 1959 by Elizabeth O. King associated with neonatal meningitis and it was named *Flavobacterium meningosepticum* (King, 1959). In 1994 a new genus was created, *Chryseobacterium*, and it was moved to this new genus: *C. meningosepticum* (Vandamme et al., 1994). Later, in 2005, the genus *Elizabethkingia* was proposed and *C. meningosepticum* was renamed as *E. meningoseptica* (Kim et al., 2005).

E. miricola was first described in 2003 as *Chryseobacterium miricola* which later, in 2005, was renamed and included in the genus *Elizabethkingia* (Li et al., 2003; Kim et al., 2005).

E. anophelis was first isolated from midgut of the mosquito *Anopheles gambiae* in 2011 (Kämpfer et al., 2011).

Finally, in 2017, three new species were proposed: *E. bruuniana*, *E. occulta* and *E. ursingii* (Nicholson et al., 2018).

Epidemiology

They are ubiquitous in nature. We find them in the soil, in both salt and fresh water, as well as in treated water, including in the tap water of hospitals. Generally, it is not found forming part of the human flora. In recent years there has been an increase in the number of cases, some of them associated with the hospital environment. The prevalence varies between geographic areas. The incidence of *E. meningoseptica* is variable and not clear but most of them are associated with hospitals (Vaneechoutte et al., 2015; Lin et al., 2018; Moore et al., 2016).

Microbiology and pathogenicity

Elizabethkingia species are gram-negative, aerobic, non-spore-forming, nonmotile, oxidase positive, catalase positive, nitrate negative and indole positive bacilli and they do not ferment glucose. The colonies on blood agar are smooth, circular, non-hemolytic and some strains are pale yellow-pigmented. The colonies are non-lactose fermenting having a pale and translucent appearance when grown on MacConkey agar. The strains cannot reduce nitrate and can hydrolyze esculin and gelatin.

Virulence factors are not well known for *Elizabethkingia* species but the ability to adapt to different environments and the existence of multi-resistant strains must be considered.

Clinical manifestations

Elizabethkingia species should be considered as a new emerging opportunistic pathogen. There are several cases associated with intensive care units and those associated with patients with underlying comorbidities or immunosuppression (Maraki et al., 2009; Weaver et al., 2010; Hsu et al., 2011).

For all six species, cases of bacteremia (associated or not with catheter), urinary tract infection and pneumonia have been described (Green et al., 2008; Jean et al., 2014; Lin et al., 2019). *E. miricola* has been isolated several times in patients with cystic fibrosis (Kenna et al., 2018). Both *E. meningoseptica* and *E. anophelis* have been isolated as causing meningitis, especially in pediatric patients (King, 1959; Frank et al., 2013; Joshi et al., 2019). They can also cause skin and soft tissue infections and other invasive infections such as bone infection (Calatrava et al., 2020). The infections are usually related to the hospital environment and many of them causing sepsis and having a high mortality rate (Jean et al., 2014; Lin et al., 2019).

Microbiological diagnosis

Overall, the usual identification methods are unreliable to identify *Elizabethkingia* species, so they are and have been misidentified. The identification performing biochemical properties has shown low correlation with the studies carried out by sequencing the 16S ribosomal RNA gene (rRNA). It has been seen that many species are misidentified as *E. meningoseptica*. The application of techniques such as MALDI-TOF mass spectrometry is useful to identify infections caused by *Elizabethkingia* species. However, MALDI-TOF systems will better or worse identify between different species according to the database they have and some errors are detected with some species. In this case, molecular methods are the techniques of choice to differentiate between the species of the genus *Elizabethkingia* (Eriksen et al., 2017; Lin et al., 2019; Burnard et al., 2020).

Treatment

Antibiotic susceptibility varies between species. Usually, isolates of the genus *Elizabethkingia* are resistant to beta-lactams.

Overall, *Elizabethkingia* species have two types of beta-lactamases; class A extended spectrum β -lactamase (ESBLs) and class B metallo-beta-lactamase (MBL), which confer intrinsic resistance to beta-lactams and carbapenems. It is typically resistant to third and fourth generation cephalosporins, carbapenems and aminoglycosides. The strains tend to be sensitive to piperacillin-tazobactam, ciprofloxacin, levofloxacin, rifampicin, trimethoprim sulfamethoxazole and minocycline. There are many genes involved in antibiotic resistance, i.e. *bla_B* and *bla_{COB}* (MBL) or *bla_{CME}* (ESBLs). Management should be based on sensitivity results of the antibiogram (Bellais et al., 2000; Yum et al., 2010; Han et al., 2016; Lin et al., 2012; Lin et al., 2019).

In this chapter we include three microorganisms that are a common cause of zoonotic related human infection: *Francisella* spp., *Brucella* spp. and *Pasteurella* spp.

These microorganisms are bacilli or coccobacilli Gram negative bacteria, with different requirements for growing on laboratory culture media. *Francisella* spp. and *Brucella* spp. share a concern for their potential use in bioterrorism.

Francisella

Taxonomy

Francisella is one of the three genera of the *Francisellaceae* family, a member of the gamma-proteobacteria. This genus comprises several species of which the most studied, because of their potential to cause human infection, are *Francisella tularensis*, *Francisella novicida*, *Francisella philomiragia* and *Francisella noatunensis*. The genus also comprises several non-classified *Francisella* species. Edward Francis, an American bacteriologist subdivided these four species into 6 subspecies (Versalovic et al., 2011; Rosenberg et al., 2013a; Parte, 2014).

Francisella tularensis is subdivided into three subspecies, two of which are in turn subdivided into several subclades. These subspecies are: *Francisella tularensis* subsp. *tularensis* (type A), which is subdivided in three subclades: A1a, A1b and A2; *Francisella tularensis* subsp. *holarctica* (type B), which is comprised by 10 subclades; and *Francisella tularensis* subsp. *mediasiatica* (Versalovic et al., 2011).

Francisella novicida is mainly isolated from water; it was originally described as *Pasteurella novicida*. The most recent additions to the genus *Francisella* are *F. hispaniensis*, isolated from human blood and *F. haliotica*, from a marine gastropod mollusk in the family Haliotidae (Rosenberg et al., 2013a).

Despite a 75% DNA relatedness and >99.8% identity in 16S rRNA gene sequences between *F. novicida* and *F. tularensis*, whole-genome comparisons provide enough evidence to consider both being two separate species (Versalovic et al., 2011).

Using pulse field gel electrophoresis, type A strains have been separated into two main genetic groups (AI and AII) and subgroups (e.g., AIa and AIb). More recent studies based on whole genome sequencing and canonical SNP (canSNP) genotyping have revealed a higher population complexity, with three main subgroups A.I.3, A.I.8 and A.I.12. Type B strains are classically separated into three biovars (I, II and Japonica). Whole genome sequencing and canSNP genotyping methods have also revealed multiple clades, including the three major subpopulations B.4, B.6 and B.12. The B.16 clade is phylogenetically more deeply rooted and correlates perfectly with biovar Japonica (Maurin, 2014).

Genus description

The *Francisella* genus bacteria are small (0.7–1.7 µm), Gram-negative bacilli or coccobacilli. These microorganisms are nonmotile, non-spore-forming, heterotrophic, strict aerobes, urease negative and weakly catalase positive. Most of the species, but not all, produce H₂S. They react with a limited number of carbohydrates and utilize a few sugars (glucose, maltose, sucrose and glycerol), also produce acid without gas. They have a relatively slow growth that can be enhanced with sulfhydryl supplementation. Less metabolically competent members of the genus require enhanced levels of cysteine or cystine in culture media (Versalovic et al., 2011; Rosenberg et al., 2013a).

Epidemiology

Francisella species are zoonotic. Mainly found in the Northern hemisphere in more than 300 species of mammals, birds, reptiles, amphibians, fish and invertebrates.

Francisellaceae is widely distributed. Some species are obligate pathogens of animals and humans (*F. tularensis*), other species are present in the environment and are opportunistic pathogen of humans (*F. novicida* and *F. philomiragia*). Other species have been associated only with animals (*F. noatunensis*) (Versalovic et al., 2011).

F. tularensis is only found in the North Hemisphere, the Holarctic region. *F. novicida* and *F. noatunensis* are both found in the North and South Hemispheres. *F. tularensis* subsp. *tularensis* is only found in North America, and *F. tularensis* subsp. *holartica* have much wider distribution. *F. tularensis* subsp. *mediasiatica* is restricted to central Asia. *F. novicida* is primarily found in North America. *F. philomiragia* is mostly found in North America, but also in central and Eastern Europe and Australia. *F. noatunensis* is isolated from Scandinavia, Chile and Japan (Versalovic et al., 2011).

In North America we only found infection caused by *F. tularensis* subsp. *tularensis* (type A) or *F. tularensis* subsp. *holartica* (type B). In Eurasia, type A is not observed; type B is the main subspecies causing disease, with fewer cases due to *F. tularensis* subsp. *mediasiatica*. Types A and B are found in USA but differ in virulence and ecological niche. Type A1a and A1b predominate in the eastern half of USA while type A2 appears restricted to the western. Type A1, which is the most virulent and invasive subspecies, is endemic in the central states, and is associated with lagomorphs, cats and ticks. Type A2 is mostly found in the western USA, and it is less virulent. Type B is associated with water bodies, rodents and ticks (Versalovic et al., 2011; Mani et al., 2016).

F. holartica is separated into three biovars. Strains from biovar 1 are erythromycin sensitive and are reported in Western Europe; strains from biovar 2 are erythromycin resistant and are found in Eastern Europe. These strains can overlap in their geographical spread. The third one, biovar japonica, is mainly found in Japan, but also reported in China and Turkey (Maurin and Gyuranecz, 2016).

There is a known focus of endemicity of tularemia in Russia, Kazakhstan, Finland and Sweden. Reports of annual cases are frequent in Eastern Europe. Tularemia cases are reported less frequently from Western Europe, however, several outbreaks have occurred in Spain (Versalovic et al., 2011).

F. tularensis has many animal reservoirs, the most often associated with tularemia in humans are small rodents, like mice, rats and lemmings, but also it can be transmitted by arthropods and mosquitoes. In Europe, the most prevalent Ixodidae ticks infected with *F. tularensis* belong to the species *Dermacentor reticulatus* and *Ixodes ricinus*. *Aedes cinereus* is the mosquito species most often associated with the transmission of tularemia in Sweden and Finland (Maurin and Gyuranecz, 2016).

The ecology of human tularemia in the USA has changed over the past century. During the first half of the twentieth century, the majority of human cases were attributed to exposure to infected lagomorphs, while during the latter part of the century, human tularemia has been predominantly a tick-borne disease (Mani et al., 2016).

The major modes of *F. tularensis* transmission to humans are direct transmission from animal reservoirs through handling or ingestion of undercooked meat from an infected animal, arthropod and mosquito bites and transmission through contaminated water and soil environments (Maurin and Gyuranecz, 2016).

Pathogenicity and clinical significance

Francisella tularensis

Francisella tularensis is one of the most infectious bacterial pathogens known, as few as 10 microorganisms delivered subcutaneously or 25 microorganisms delivered by inhalation can lead to life threatening infection in humans. It is considered a potential bioterrorism agent due to its high infectivity and lethality, and the ease with which it can be dispersed (Maurin, 2014; Clemens et al., 2018).

F. tularensis is an intracellular pathogen that infects several types of cells: endothelial cells, alveolar type II cells, neutrophils and hepatocytes, but it is in macrophages where it replicates, and these cells are considered to be the vehicles for bacterial dissemination within the host. Two subspecies, *F. tularensis* subspecies *tularensis* (type A) and *F. tularensis* subspecies *holarctica* (type B) causes human tularemia (Kingry et al., 2014; Kinkead and Allen, 2016).

Tularemia is a serious and potentially life-threatening disease in humans. It has a short incubation period, usually from 3 to 5 days, but with a maximum of 2 weeks. It has been known by a number of synonyms attesting to the variety of clinical presentations, the ubiquitous presence in nature of the infectious agent and the means by which humans may acquire the infection, some of these names are rabbit fever, deerfly fever, Ohara's disease, glandular type of tick fever, ... (Versalovic et al., 2011; Rosenberg et al., 2013a; Maurin and Gyuranecz, 2016).

First, *F. tularensis* multiplies at the site of inoculation, where it causes an acute inflammatory reaction which involves neutrophils, macrophages and lymphocytes, and can lead to tissue necrosis. Then it can spread to regional lymph nodes and may then spread systemically through a lymphohematogenous route. Macrophage uptake is a unique process called "looping phagocytosis" that involves pseudopod loops. This entry is dependent upon complement and complement receptors. It also may be directly transferred from infected cells to uninfected macrophages during exchange of cytosolic material. After being taken up, phagosome maturation and phagosome-lysosome fusion are impaired and *F. tularensis* escapes into the cytosol inducing macrophage cell death and release of bacteria. Neutrophils are also unable to kill *Francisella* because it inhibits NADPH oxidase, repressing the oxidative burst. *F. tularensis* also can inhibit apoptosis and prolong survival of infected neutrophils (Clemens et al., 2005, 2018; Kinkead and Allen, 2016).

The clinical spectrum of tularemia depends on the mode of acquisition, the virulence of the infecting strain, the immune status of the host and timely diagnosis and treatment. Tularemia can be misdiagnosed since its symptoms are not unique. The differential diagnosis includes cat scratch fever, mycobacterial infections, anthrax, brucellosis, legionellosis and plague. Early clinical presentation corresponds to influenza-like symptoms (fever, chills, headache, myalgia and arthralgia). Infections can initiate through the skin, mucosal membranes, lungs and gastrointestinal tract, to produce different tularemia manifestations depending on the site of infection: ulceroglandular, glandular, oropharyngeal, oculoglandular and pneumonic forms. The ulceroglandular is the most common form (45–80% of the reported cases), the usual portal of entry is via arthropod bite or other inoculation through the skin barrier. This form combines a skin inoculation long-lasting ulcer with chronic suppuration, and a localized lymphadenopathy. An isolated lymphadenopathy without detectable skin ulcer corresponds to the glandular form. The oropharyngeal form comprises chronic pharyngitis occurring after oral contamination due to ingestion of contaminated water or food, sometimes with mucosal ulcers and often with swollen and painful cervical lymph nodes. The oculoglandular form is a painful conjunctivitis with localized lymphadenopathy occurring after conjunctival contamination, usually as a result of the mechanical transfer from an infectious source to the eye by the fingers. Pneumonic tularemia is acquired through inhalation of a contaminated aerosol or through hematogenous spread. It is the most severe form of the disease. There is also a Typhoidal tularemia which is a severe systemic disease with acute onset, high fever, headaches and neurological symptoms, but no localized lesions (nor skin ulcers, nor lymphadenopathy). It is the most difficult form to recognize because there is no identified portal of entry and localized signs are absent. If untreated, bacterial dissemination can lead to secondary clinical presentations, such sepsis and meningitis (Versalovic et al., 2011; Rosenberg et al., 2013a; Maurin and Gyuranecz, 2016).

The severity can range from mild and self-limiting to fatal and is largely dependent on the infecting strain. Little tularemia-related mortality is reported in Europe and Asia, where only *F. tularensis* subsp. *holarctica* causes tularemia, while in the USA, where tularemia is caused by *F. tularensis* subsp. *tularensis*, the mortality ranges from 2.3% to 9%. Among *F. tularensis* subsp. *tularensis* clades, type A1b shows a significantly higher mortality (24%) compared to types A1a (4%) and A2 (0%) (Kugeler et al., 2009; Versalovic et al., 2011; Kingry et al., 2014).

Other Francisella species

- *Francisella novicida*, *F. philomiragia*, *F. hispaniensis* and *F. opportunistica* are rarely associated with human disease and cases that do occur are associated with immunocompromised patients or patients that have other underlying health problems (Huber et al., 2010; Kingry et al., 2014; Siebert et al., 2020).
- *Francisella novicida*: rare opportunistic human pathogen. Usually causes disease in immunocompromised patients. Disease in healthy individuals it is being associated to consumption of contaminated water or following near-drowning events (Kingry et al., 2014; Siebert et al., 2020).
- *Francisella philomiragia*: it is commonly found in soil and water. It is an opportunistic pathogen that infect immunocompromised patients, but also causes disease in healthy individuals after near-drowning accidents (Siebert et al., 2020).

- *Francisella hispaniensis*: it was first isolated from the blood of a patient in Spain. Only two cases have been reported. The second one was a male fisherman with a cutaneous ulcer in China. It is considered an emerging human pathogen, but its epidemiology and pathogenicity are still unknown (Huber et al., 2010; Zhou et al., 2020).
- *Francisella opportunistica*: it was first isolated from cerebrospinal fluid and blood from two immunocompromised patients in the USA. There are no additional reports of this species causing disease in humans (Kugeler et al., 2008; Dietrich et al., 2020).

Diagnosis

Collection and transport of specimens

Francisella spp. has an extremely low infectious dose and cultures have a high concentration of microorganism so it must be handled with great precaution. Tularemia has been commonly reported as a laboratory associated infection. Clinical specimens should be handled under biosafety level 2 (BSL-2) conditions and go into biosafety level 3 as soon as a suspect *Francisella tularensis* is isolated in culture (Versalovic et al., 2011).

The clinical specimen for diagnostic should be chosen accordingly with the clinical form of the disease (sputum, aspirates, local and lesions swabs, biopsies, whole blood, serum. . .). Whole blood could be used for all clinical forms, but it could be negative at the early stages of the disease. The specimens should be delivered to the laboratory within 24 h (preferably within 2 h), swabs in an appropriated transport medium as Amies, and if the transport is delayed, specimens should be stored at 2–8 °C. *F. tularensis* can survive up to 7 days at room temperature when placed in Amies medium, but Stuart medium or saline are inadequate for keeping it viable. Aspirates, respiratory secretions and biopsies should be collected into sterile containers. If biopsies are too small, saline should be added to keep them moist. Serum samples should be separated from blood as soon as possible and stored at 2–8 °C for up to 10 days, or frozen (WHO, 2007; Versalovic et al., 2011; Maurin and Gyuranecz, 2016).

Direct detection in specimens

Fresh clinical specimens can be directly examined by microscopy after a Gram staining, but it has little diagnostic value due to the small size of *Francisella* spp. and their poor staining with safranin. It can be improved by using basic fuchsin but remains a poor diagnostic method. Antigen detection by DFA staining with fluorescein isothiocyanate-labeled hyperimmune rabbit polyclonal antibody directed against whole killed *F. tularensis* cells can presumptively identify *F. tularensis* in clinical specimens. DFA can also confirm the identification of recovered isolates, as well as slide agglutination. Immunohistochemical staining using monoclonal antibody against the lipopolysaccharide (LPS) can be used to visualize *F. tularensis* in formalin-fixed tissues (WHO, 2007; Versalovic et al., 2011).

Molecular detection is a valuable diagnostic tool. PCR methods have been used mainly for diagnostic of the most prevalent form, ulceroglandular tularemia. The majority have been conventional PCR assays targeted at *fopA* and *tul4* genes. The *tul4* PCR has been validated with wound specimens from patients with ulceroglandular tularemia and displays a sensitivity of 75%, greater than culture (sensitivity of 62%). There is also a real-time TaqMan PCR assay, with increased specificity, that includes multiple target genes (*ISFtu2*, *iglC*, *tul4*) and can be applied to different clinical specimens (aspirates, bronchial washes, ulcer swabs, . . .) (WHO, 2007; Versalovic et al., 2011).

Culture isolation and identification

Culture provides a conclusive diagnosis, but *F. tularensis* is a fastidious microorganism that requires cysteine or cystine supplementation to grow on artificial medium. It could grow on chocolate agar, buffered charcoal yeast extract (BCYE), Thayer-Martin, and thioglycolate broth. It also can grow on general media supplemented with 1–2% IsoVitalEx. Subcultures must be performed on cysteine-enriched media as *F. tularensis* will usually lose its viability with continued passage. There is a specialized medium of cysteine heart agar supplemented with 9% of chocolated sheep blood (CHAB) where *F. tularensis* displays a distinctive colony morphology that can aid in its identification (green, opalescent, raised, shiny colonies). The organisms grow slowly (60 min generation time), so cultures must be kept a minimum of 48 h incubated at 36 °C ± 1 °C aerobically and observed daily for up to 14 days. Clinical samples from non-sterile sites should be plated on antibiotic-containing media, such Thayer-Martin or BCYE, in order to prevent the microbiota from overwhelming *Francisella* (WHO, 2007; Versalovic et al., 2011; Rosenberg et al., 2013b).

Suspicion of *F. tularensis* may be raised when small gray-white colonies (1–2 mm) grow on chocolate agar after 48 h and scant to no growth on blood agar is observed. *F. tularensis* is oxidase negative, weakly catalase positive, beta-lactamase positive; X and V factor negative and urease negative. Some of these tests can help differentiate it from other similar gram-negative organisms as *Haemophilus influenzae* or *Brucella* spp. On chocolate agar, BCYE and Thayer-Martin, *F. tularensis* colonies are gray to white, smooth, raised and moist. *F. novicida* and *F. philomiragia* are cysteine independent and grow more robustly, with a >5 mm on chocolate agar after 24–48 h (WHO, 2007; Versalovic et al., 2011).

Identification of isolates can be achieved using antigen or molecular detection methods, as well as matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF MS).

Serologic test

Clinically significant antibody titers may be detected on the first week after onset of symptoms and peak at 3–4 weeks. Residual titers might persist for over 10 years. Immunoglobulins, IgM, IgA and IgG may appear at the same time and IgM can last months to

years, so its presence does not always indicate early or recent infection. Various immunoassays have been used for serological diagnosis of tularemia, including microagglutination, ELISA and western blot. These tests have a high specificity but can cross-react with some other microorganisms as *Brucella* spp. (WHO, 2007; Versalovic et al., 2011; Rosenberg et al., 2013b; Maurin and Gyuranecz, 2016).

Antibiotic susceptibility testing and treatment

The Clinical Laboratory Standards Institute (CLSI) establish that the antibiotic susceptibility testing of *Francisella tularensis* strains should be performed using Mueller-Hinton broth enriched with 2% defined growth supplement. The pH must be adjusted to 7.1 ± 0.1 after addition of growth supplement. The inoculum should be calibrated at 5×10^5 CFU/mL of final concentration. Incubation in 5% CO₂ enriched atmosphere may lead to acidification of the medium and overestimation of aminoglycoside and macrolide MICs, or underestimation of tetracyclines MICs (Caspar and Maurin, 2017).

The European Committee on Antimicrobial Susceptibility Testing (EUCAST) does not have antibiotic break-points nor recommendations on antibiotic susceptibility testing for *Francisella* spp.

Several agar media were used for MIC determination using the *E*-test strip method, appearing to be a convenient alternative to the broth microdilution method, however it has not been standardized (Caspar and Maurin, 2017).

Antimicrobials with well-established clinical efficacy include aminoglycosides, tetracyclines, fluoroquinolones and chloramphenicol. Resistance to these drugs has not been reported. Among antibiotic recommended for first-line treatment of tularemia, ciprofloxacin displayed the lowest MICs ranges. The other most active fluoroquinolone is levofloxacin. Streptomycin is the preferred aminoglycoside because its high efficacy, however, gentamicin is more available and has less vestibular toxicity. Chloramphenicol use is restricted to meningitis, because of potential bone marrow toxicity. Beta-lactams have been associated with clinical failure. Two β -lactamase genes (*bla1* and *bla2*) have been found in the Live Vaccine Strain (LVS). A class A β -lactamase (FTU-1) is present in, at least, 14 strains of *F. tularensis* subspecies and corresponds to the *bla2_{LVS}* gene. There has been other β -lactam resistance mechanisms described that conferred resistance to all β -lactams, therefore, these antimicrobials are not recommended to treat tularemia (Penn, n.d.; Versalovic et al., 2011; Caspar and Maurin, 2017).

Antimicrobial susceptibility testing of *F. tularensis* is not usually performed in clinical microbiology laboratories because of safety concerns and because resistance to antibiotics used for tularemia treatment has not been reported (Versalovic et al., 2011).

Brucella

Taxonomy

Brucella genera belong to the *Brucellaceae* family along with other free living soil organisms like *Ochrobactrum* and *Mycoplana* genera. The *Brucellaceae* are part of the order *Rhizobiales* (which includes other genera that causes human disease like *Bartonella* and *Roseomonas*) in the class *Alphaproteobacteria* of the phylum *Proteobacteria*. Other organisms that cause human disease in the *Alphaproteobacteria* class are, for example, the genera *Rickettsia* and *Ehrlichia* (Ficht, 2010; Versalovic et al., 2011).

The different species of *Brucella* show more than 90% similarity at the genome level which leads some authors to propose that *Brucella* are actually one species composed by biovars of *B. melitensis*, but as the distinct species display different host preferences and virulence, separating the genus based on phenotypic characteristics is more compelling (Versalovic et al., 2011; Olsen and Palmer, 2014; Suárez-Esquivel et al., 2020).

As of today, the genus *Brucella* comprises 12 species, nine terrestrial and three marine (Table 1).

Table 1 *Brucella* species and preferred hosts.

	Species name	Biovars	Preferred hosts
Terrestrial	<i>Brucella melitensis</i>	Three	Goats, sheep, camels
	<i>Brucella abortus</i>	Seven	Cattle, bison, buffalo
	<i>Brucella suis</i>	Five	Swine and wild animals
	<i>Brucella canis</i>		Dogs
	<i>Brucella ovis</i>		Rams
	<i>Brucella neotomae</i>		Desert and wood rats
	<i>Brucella papionis</i>		Baboons
	<i>Brucella vulpis</i>		Foxes
	<i>Brucella inopinata</i>		Unknown
	<i>Brucella delphini</i>		Marine mammals
Marine	<i>Brucella pinnipediae</i>		
	<i>Brucella cetaceae</i>		

Versalovic et al. (2011) and Whatmore et al. (2016).

Genus description

Brucella are small (0.5–1.5 µm), nonmotile, facultative intracellular Gram-negative coccobacilli that lack capsules and do not form spores. These bacteria are slow-growing and aerobic, but some prefer CO₂ atmosphere for their growth. *Brucella* species are catalase and oxidase positive, do not ferment sugars and can grow on wide range of culture media. Urease activity differs between species and biovars (*B. suis* and *B. canis* give strong reaction within minutes). *Brucella* spp. may occur either as smooth or rough strains depending on the presence of LPS. Rough strains contain little LPS and are less virulent than smooth strains (Versalovic et al., 2011; Percin, 2013; Castaño et al., 2016; Yagupsky et al., 2020).

Epidemiology

Brucellosis is one of the most important zoonotic diseases and is reemerging in some countries. It is endemic in the Mediterranean basin, Middle East, Central Asia, China, Indian subcontinent, sub-Saharan Africa, Mexico and Central and South America. It causes more than 500,000 infections annually worldwide, mostly in agrarian societies and places where handling of animal products such as dairy products is less strict (Olsen and Palmer, 2014; Al-Nassir, 2017; Bosilkovski, 2020).

Worldwide, *Brucella melitensis* is the most prevalent species causing human brucellosis and it is the most virulent. It is normally associated with infection in sheep and goats, but other species can be infected. In the Middle East, *B. melitensis* infection of cattle is an emergent problem (Corbel, 2006).

Brucella abortus is the most widespread, but associated with much less human disease. Cattle is the most common source, but other animals are an important sources in some areas (Corbel, 2006).

Brucella suis is more restricted but can cause severe human disease. Biovars 1 and 3 are zoonotic; the preferred hosts are domestic pigs, are mainly present in the United States, Australia and China and are highly virulent. Biovar 2 is mainly restricted to hares and wild boars in Europe and Asia, it rarely infects humans. Biovar 4 infects reindeer and caribou and is a zoonotic risk in the Arctic region. Biovar 5 usually infect rodents in Eastern Europe and seems confined to their natural hosts, human infection is rarely reported (Corbel, 2006; Suárez-Esquivel et al., 2020).

Brucella canis is widespread in dogs, but rarely produces disease in humans (Corbel, 2006).

Human brucellosis occurs among the general population in endemic areas, with no differences among sexes nor ages and it is mostly due to ingestion of unpasteurized goat, sheep, cow and camel milk or its products. Human infection can also occur by direct contact with tissues or fluids associated with abortion in infected animals, such exposure is more common seen in non endemic areas and it is occupational related (e.g., veterinarians, abattoir workers, clinical and research microbiology staff, ...). *Brucella* spp. can survive for long periods in dust, water, soil, meat and dairy products. Infection is acquired through direct damage skin contact, inhalation of aerosolized infected particles or mucosal accidental inoculation. Human-to-human transmission of brucellosis has been reported through breast milk and venereal transmission, which is very rare, but blood donation and bone marrow transplant are of more potential significance as a source of infection (Corbel, 2006; Versalovic et al., 2011; Olsen and Palmer, 2014).

Pathogenicity and clinical significance

Brucella spp. enters the host via inhalation, ingestion or through damaged skin. Once the bacteria penetrate the mucosal epithelium they encounter polymorphonuclear and mononuclear phagocytes, then *Brucella* spp. inhibit the phagosome-lysosome fusion escaping from phagocytic killing and evading the immune system. This allows the bacteria to be transported to regional lymph nodes within phagocytes, which will result in lymph node hypertrophy and inflammation. If the local infection it is not resolved rapidly, the bacteria will spread via blood or lymph to other tissues and organs, with tropism for the reticuloendothelial system, where it will replicate, resulting in different clinical phases of the disease (Versalovic et al., 2011; Olsen and Palmer, 2014).

In animals, brucellosis is usually sub-acute or chronic. In sexually mature animals, the infection localizes in the reproductive system causing placentitis in the pregnant female, followed by abortion, and epididymitis and orchitis in the male. Although abortion or premature birth are characteristic, in some areas are relatively uncommon, being hygromas and abscesses the major clinical signs (Corbel, 2006).

The clinical categories of human brucellosis are based on arbitrary criteria and there is not uniform definition. Some authors describe them based on the duration of manifestations: acute (≤ 2 months), subacute (2–12 months) and chronic (≥ 12 months); other based on clinical manifestation: subclinical, localized, chronic and active (Versalovic et al., 2011).

Human brucellosis has an incubation period that varies from 1 to 4 weeks, with an insidious onset on almost half the cases. It presents with a wide spectrum of nonspecific clinical manifestations, such as fever, sweats, arthralgia, myalgia, fatigue, weight loss, hepatomegaly and splenomegaly. Usually, patients feel better in the morning, with symptoms worsening as the day progresses. The pattern of the fever presents with peaks and valleys ("undulant fever") over several days if untreated (Corbel, 2006; Versalovic et al., 2011).

Brucella virulence factors include urease (to avoid stomach stress through oral passage) and vacuoles that enable the escape from immune system recognition and provide acidic environment to hamper antibiotic activity. *Brucella* has several antigens characterized. The LPS is the major one, and dominates antibody response. Based on their O side chain, smooth strains were reported to be composed of two antigenic epitopes (A, in *B. abortus*, and M, in *B. melitensis*). *Brucella* LPS O-polysaccharide appears to be the key for interaction with lipid rafts on host cells and prevents complement-mediated bacterial lysis and host cell apoptosis. It also is a poor

inducer of gamma interferon and tumor necrosis factor alpha, both of which are essential for T-helper 1 mediated immunity. The outer membrane protein 25 (OMP 25) has also been reported as a helper in surviving within mononuclear phagocytes (Versalovic et al., 2011; Olsen and Palmer, 2014).

The most common focal complications are osteoarticular, genital (both males and females), neurological, cardiac, pulmonary and renal. Mortality is very low and is mostly associated to cardiac complications (Versalovic et al., 2011).

Brucellosis during pregnancy carries the risk of spontaneous abortion during the early trimesters or vertical transmission to the fetus. Very rare transmission through breastfeeding has been reported (Corbel, 2006).

- Osteoarticular complications: It occurs mostly as arthritis, up to 70% of cases, and rarely as osteomyelitis, less than 1%. Sacroiliitis is especially common and presents with fever and back pain, often radiating down the legs (sciatica). Other joints commonly affected are, in descending order, knee, hip, vertebra and ankle. It can be misdiagnosed as rheumatoid arthritis, tuberculosis and other entities (Corbel, 2006; Versalovic et al., 2011).
- Gastrointestinal complications: As brucellosis is often foodborne, it could present with nausea, vomiting and abdominal discomfort. It resembles typhoid fever because systemic symptoms predominate over gastrointestinal ones (Corbel, 2006).
- Hepatobiliary complications: *B. abortus* may cause granulomas that are indistinguishable from sarcoidosis lesions. *B. melitensis* causes small foci of inflammation, resembling viral hepatitis. *B. suis* could cause chronic suppurative lesions and hepatic abscesses. Brucellosis may present with acute and chronic cholecystitis (Corbel, 2006).
- Respiratory tract complications: As brucellosis can be acquired through aerosol inhalation, pulmonary complications may be present, such as paratracheal lymphadenopathy, interstitial pneumonitis, bronchopneumonia, lung nodules and empyema. *Brucella* is rarely isolated from expectorated sputum (Corbel, 2006).
- Genitourinary complications: In males are mostly orchitis, usually unilateral, and epididymitis. In females, abortion in the first trimester. Other less common complications are cervicitis, salpingitis and abscesses (Corbel, 2006; Versalovic et al., 2011).
- Neurological complications: Neurobrucellosis can affect both adults and children with diverse symptoms (fever, headache, meningeal signs, coma or paresis). Direct invasion of the central nervous system occurs about 5% of cases of *B. melitensis*. *Brucella* meningitis can be acute or chronic. Analysis of cerebrospinal fluid (CSF) reveals an elevated protein content with normal or low glucose concentration and lymphocytic pleocytosis. The yield of *Brucella* culture from CSF is very low, but specific antibodies can be found in CSF and serum (Corbel, 2006; Versalovic et al., 2011).

Relapse is one of the most important features of brucellosis. Factors associated with it include the use of less effective antibiotic therapy, positive blood culture during the initial presentation and less than 10 days duration of symptoms before treatment initiation (Versalovic et al., 2011).

Diagnosis

Collection and transport of specimens

Collection of specimens of adequate volume should be performed prior to initiation of antimicrobial therapy. Specimens can be sent for culture, serology and molecular testing. Culture can be performed on many different specimens, such as blood, serum, bone marrow, CSF, other sterile body fluids, urine, abscesses and tissues. Specimens should be sent to the laboratory within 2 h, if not, they should be refrigerated. Since brucellosis is highly contagious, specimens from a patient suspected to have brucellosis should be labeled appropriately, specifying that brucellosis should be ruled out (Versalovic et al., 2011).

Direct detection in specimens

There are several gene targets in *Brucella* that can be used for detection using real-time PCR (BCS P31, BP26, 16 rRNA and IS711), but the sensitivities have a great variation and there is no standardization, so their use is relegated mostly for investigation and for reference laboratories (Versalovic et al., 2011).

Culture isolation and identification

Culture is the gold standard for brucellosis diagnosis. *Brucella* is a Class 3 pathogen and specimens should be handled with precaution in a biosafety cabinet (Versalovic et al., 2011; Percin, 2013).

Since human brucellosis always involves a bacteriemic stage, peripheral blood cultures are a suitable tool for microbiological confirmation of diagnosis. Although the sensitivity varies widely due to diverse factors like the *Brucella* species causing the disease, the duration of symptoms, volume of blood collected for culture, number of cultures obtained, blood culture system, incubation period and the performance of subculture (Percin, 2013; Yagupsky et al., 2020).

It usually takes long incubation times due to the slow growing nature of *Brucella* spp. The yield of culture is higher among patients with acute disease and bone marrow cultures demonstrate to have a 20% higher sensitivity than peripheral blood cultures (Versalovic et al., 2011).

Blood cultures using a continuously monitored system such as Bactec (BD Diagnostics, Sparks MD) and BacTAlert (bioMérieux, Durham, NC) show high sensitivities and detect bacterial growth within 1 week. There is no need to incubate bottles longer than 14 days. Subculture should be performed on conventional blood enriched media such as blood agar or chocolate agar, incubated at 36 ± 1 °C in aerobic conditions, but better with a 5% CO₂ enriched atmosphere, there is no need to keep subcultured plates longer than 4 days before discarding them as negative. CSF and other sterile body fluids can be inoculated into blood culture bottles (Versalovic et al., 2011; Percin, 2013; Yagupsky et al., 2020).

Table 2 *Brucella* species phenotypic features.

Brucella species	Growth on dyes			Agglutination in serum			H ₂ S production	Urease activity (time to positivity)	CO ₂ requirement
	Thionin	Basic Fuchsin	Safranin	A (abortus)	M (melitensis)	R (rough)			
<i>B. melitensis</i>	+	+	+	–	+	–	–	+ (24 h)	–
<i>B. abortus</i>	–	+	+	+	–	–	+	+ (24 h)	+/v
<i>B. suis</i>	+	–	–	+	–	–	–	+ (15 min)	+/v
<i>B. neotomae</i>	–	–	ND	+	–	–	+	+ (ND)	–
<i>B. canis</i>	+	–/v	–	–	–	+	–	+ (15 min)	–
<i>B. ovis</i>	+	–	ND	–	–	+	–	–	+

+, positive; –, negative; v, variable (mostly among biovars); ND, no data (Percin, 2013; Castaño et al., 2016; Yagupsky et al., 2020).

For the isolation of *Brucella* from samples contaminated with local microbiota, selective media containing antibiotics such as Thayer-Martin or Martin-Lewis can be used. Specimens inoculated directly onto solid media should be incubated at 36 ± 1 °C in a 5% CO₂ enriched atmosphere, for up to 14 days (Versalovic et al., 2011; Percin, 2013).

Brucella species colonies are usually raised and convex, 1–2 mm in diameter, smooth and glistening after 24–48 h of incubation on blood agar and chocolate agar. Rough variants can occur with *B. canis*. *Brucella* fails to grow on MacConkey agar, what can help for discriminating *Brucella* spp. from *Bordetella* spp. *Brucella* spp. are oxidase and catalase positive, majority of species are urease positive, and all are indole negative and Voges Proskauer negative. Catalase test is particularly dangerous because it is strongly positive in *Brucella* and causes aerosolization of microorganism when bubbling, every test should be performed into a biosafety cabinet. Gram staining demonstrates single, Gram-negative coccobacilli of 0.5–0.7 µm × 0.6–1.5 µm size. For confirmation and identification to the species level, slide agglutination can be performed with monospecific antiserum for *B. abortus* and *B. melitensis*, susceptibility to lysis by different phages and incubation in the presence of different dyes, such as basic fuchsin, thionin or safranin, but PCR remains as the best method to differentiate *Brucella* at the species level. Table 2 shows different phenotypic features of some *Brucella* species (Versalovic et al., 2011; Percin, 2013; Castaño et al., 2016; Bosilkovski, 2020; Yagupsky et al., 2020).

Serologic test

Human immune response to *Brucella* is characterized by an initial production of IgM, followed by appearance of IgG within 10–14 days. The general evolution of these immunoglobulins depends on response to treatment. Persistence of IgG and IgM for months (sometimes years) is observed in about 20% of asymptomatic patients who have undergone treatment and cure (Corbel, 2006; Versalovic et al., 2011).

There is no gold standard in serodiagnostic of brucellosis, consequently these tests must be evaluated by comparing results with other serological assays (Yagupsky et al., 2020).

Several antigens are used for serologic diagnostic assays, LPS is used mainly in ELISAs (Versalovic et al., 2011).

The most common test are serum agglutination test (SAT) and enzyme-linked immunosorbent assays (ELISAs). Rose Bengal agglutination test and immunochromatographic lateral flow assay are commonly used as screening tools due to their short turnaround time. Other test used for confirmation are the 2-mercaptoethanol (2-ME) agglutination test, the immunocapture agglutination test (Brucellacapt) and the indirect Coombs test. ELISA and indirect fluorescent antibody (IFA) tests can differentiate the type of antibody involved, while agglutination-based tests cannot (Bosilkovski, 2020).

- Serum agglutination test (SAT) is a tube agglutination commonly used for diagnosing *B. melitensis*, *B. abortus* and *B. suis* infections. SAT detects antibodies to brucellar smooth LPS, so it is not useful for rough *B. canis*. In general, positive SAT titers consists of >1:160 outside endemic regions and >1:320 within endemic areas. A fourfold or greater increase in titer between acute and convalescent phase serum specimens obtained at least 2 weeks apart is indicative of brucellosis, but this approach may delay therapy (Bosilkovski, 2020; Yagupsky et al., 2020).
- Rose Bengal test (RBT) is an agglutination test that detects agglutinating and non-agglutinating antibodies and does not have the drawback of the prozone phenomenon like the SAT does. The RBT has a high sensitivity (>99%) for all stages of the infection, but it has cross-reactivity with some bacteria. To provide quantitative information, after a positive RBT result, serum may be subjected to twofold dilutions and rested, positive reactions at a $\geq 1:8$ dilution correlated with acute disease and lower titers suggested contact with the organism without clinical disease but requires further investigation (Yagupsky et al., 2020).
- 2-mercaptoethanol (2-ME) agglutination test is performed identically to SAT and is run in parallel. Lately, 2-ME has been replaced by dithiothreitol (DTT) because is less toxic and also inactivates IgM antibodies, eliminating this way the cross-reactivity and the confounding caused by IgM long persistence. This assay is mainly used for serological monitoring of the response to antibiotic treatment. A 2-ME titer of $\leq 1:20$ is considered negative, titers between 1:40 and 1:80 are indicative of active brucellosis in low incidence regions, and titers $\geq 1:80$ are interpreted as diagnostic in endemic areas (Yagupsky et al., 2020).

- Coombs antiglobulin agglutination test consist of serial dilutions of patients sera. This test is useful for confirmation of brucellosis because it can detect incomplete antibodies. It is generally ordered in patients with chronic brucellosis and in relapses (usually with titer of 1:80 or greater). There is a modified Coombs test, the Odak test, that is performed in microcolumns with gel matrix and Coombs antibodies, which is more rapid and simple, but more experience is needed (Yagupsky et al., 2020).
- Complement fixation (CF) test consists in a serial dilution of patient sera, previously inactivated by heat (56 °C, 30–60 min). If IgG1 isotype antibodies are present in patients' sera, they will attach to the antigen, the complement will be activated and no residual complement will remain for lysing the erythrocytes. If no antibodies are present, the hemolysis will occur. The resulting hemoglobin concentration represents an inverse measure of antibody activity in the serum. This test it is used to diagnose brucellosis in livestock, but it is not used in clinical laboratories to diagnose human infection due to its technical complexity and lack of standardization (Yagupsky et al., 2020).
- Immunocapture agglutination test is a single-step assay (Brucellacapt test; Vircell, Santa Fé, Granada, Spain) recently introduced for serodiagnostic of human brucellosis. It operates in acidic medium to avoid the low specificity of IgM, and uses *B. abortus* as antigen. This assay detects agglutinating IgG and IgM, and non-agglutinating antibodies to the three *Brucella* species with smooth LPS strains. In general, the titers obtained with this assay are concordant with those in the Coombs test in the early stages of infection. Titers $\geq 1:640$ are observed in long evolution brucellosis with non-diagnostic SAT titers ($< 1:160$). If the antimicrobial therapy is successful, Brucellacapt titers decrease rapidly (Yagupsky et al., 2020).
- ELISAs can detect different immunoglobulins using LPS or cytosolic proteins as antigen, but it is also used to detect the IgG avidity. It is performed in microtiter plates coated with *Brucella* antigen, filled with serially diluted patients' sera and incubated. For the IgG avidity assay, pairs of wells of a microtiter plate coated with *B. abortus* LPS are incubated with the patients' sera. For each serum, one well is washed with phosphate-buffered saline (PBS) and the other well is washed with highly concentrated urea in PBS. Low-affinity antibodies are removed from the binding sites by the urea, leaving only the high-affinity ones attached to solid phase. Then, the ELISA for IgG is performed. The avidity index (AI) is calculated by dividing the absorbance of urea-treated microwells by the absorbance of untreated wells and multiplying by 100. A high AI suggest immunological memory, thus a advance infection, whereas a low AI is consistent with recent infection (Yagupsky et al., 2020).

Usually, brucellosis diagnosis by serology testing it is done by a combination of two of these tests. This approach also give us an idea of the stage of the disease: in acute disease any of the assays may be positive, but in chronic, complicated or focal disease, SAT may be negative while 2-ME, Brucellacapt, Coombs and ELISA IgG may be positive (Bosilkovski, 2020).

ELISAs measure IgM, IgG, and IgA, and typically use whole cells or purified lipopolysaccharide (LPS), protein extracts as well as other antigens. The sensitivity of ELISA IgM or IgG is lower than SAT (45% and 79% versus 95%, respectively), but if ELISA IgM and IgG are used in combination, the sensitivity and specificity were comparable with SAT (94% and 97%, respectively) (Castaño et al., 2016).

The Brucellacapt and indirect Coombs tests have similar sensitivity and specificity; the Brucellacapt is more rapid and less cumbersome to perform (Castaño et al., 2016).

There are many disadvantages associated with serologic tests, like cross-reactivity with other bacteria, which is a problem especially with standard tube agglutination. Cross-reacting organisms include *Francisella tularensis*, *Yersinia enterocolitica*, *Escherichia coli*, *Salmonella urbana*, *Vibrio cholerae*, and others. False-negative results are common in the early stages of infection, in immunosuppressed patients and in the presence of incomplete or blocking antibodies. In addition, a "prozone" phenomenon (the inhibition of agglutination at low dilutions due to an excess of antibodies or to nonspecific serum factors) may also be observed with serum agglutination testing (Castaño et al., 2016).

The interpretation of serologic tests can be difficult in the setting of chronic infection, reinfection, relapse, and in endemic areas with a high seroprevalence. Positive serologic test results can persist long after recovery in treated individuals, so it is not always possible to distinguish serologically between active and past infection (Castaño et al., 2016).

Antibiotic susceptibility and treatment

Routing susceptibility testing of *Brucella* spp. is not indicated due to poor correlation between *in vitro* activity and clinical efficacy, laboratory safety concerns and the rare development of antibiotic resistance against the main antimicrobials used in its treatment (Versalovic et al., 2011).

Tetracyclines, especially minocycline and doxycycline, are the most effective drugs for brucellosis. Defervescence usually occurs within the first week of treatment, but six o more weeks are required. Because the relapse with tetracycline monotherapy is about 10–20%, most authorities recommend combination with aminoglycosides, rifampicin, trimethoprim-sulfamethoxazole or quinolones. The most effective regimen in adults without complications is combined doxycycline for 45 days with streptomycin for 14 days or gentamicin for 7 days. A good alternative is the combination of doxycycline and rifampicin for 45 days. A secondary alternative therapy is the use of fluoroquinolones or trimethoprim-sulfamethoxazole in combination with other drugs (doxycycline or rifampicin). These antibiotics should be used always in combination therapy due the high rate of relapse when used alone. The duration of therapy must be individualized attending to the complications that may be present, thus neurobrucellosis and spondylitis usually require longer courses of antibiotherapy (Corbel, 2006; Castaño et al., 2016).

Pasteurella

Taxonomy

The genus *Pasteurella* belongs to the *Pasteurellaceae* family. The main specie causing human infection is *Pasteurella multocida*, which is separated into three subspecies: *multocida*, *septic* and *gallicida*. Other species isolated from humans are *P. canis*, *P. dagmatis* and *P. stomatis*. *Pasteurella multocida* has a high genotypical homogeneity, but its phenotypic characteristics allow to differentiate diverse lineages (Versalovic et al., 2011).

Pasteurella multocida strains are classified into five serogroups based on capsule antigens: A, B, D, E and F. Each is generally associated with a specific host, although not completely restricted to them (Ewers et al., 2006; Harper et al., 2006).

Genus description

Pasteurella spp. are small, pleomorphic, nonmotile, non-spore-forming, Gram-negative coccobacilli. *P. multocida* is facultatively anaerobic, grows well on blood agar, chocolate agar, Mueller-Hinton agar and brain-heart infusion (BHI), but it shows no growth on MacConkey agar. It can be seen as a single bacillus, in pairs, in short chains and in clusters. Bipolar staining with Giemsa or methylene blue is frequent (Versalovic et al., 2011; Wilson and Ho, 2013; Mogilner et al., 2019).

Epidemiology

Pasteurella spp. are distributed worldwide. It is part of the normal oral, nasopharyngeal and upper respiratory tract microbiota of fowl and mammals. Dogs and cats have the highest carriage rate of *P. multocida*. It is associated with several distinct disease syndromes. In animals it causes avian cholera, which is a systemic disease that all bird species appear to be susceptible to, hemorrhagic septicemia, atrophic rhinitis, snuffles and pneumonia. Zoonotic transmission to humans is mostly from direct contact with oral or nasal secretions of animals. Generally occur after cat or dog bites or scratches, but also from licking of wounds or injured skin (Wilkie et al., 2012; Wilson and Ho, 2013; Mogilner et al., 2019; Weber and Kaplan, 2019).

Pathogenicity and clinical significance

Many virulence factors are described in *P. multocida* such as capsule, LPS, adhesins (fimbria), toxins (PMT), iron-regulated and iron acquisition proteins and several membrane proteins (OMPs) (Peng et al., 2019).

Pasteurella multocida is associated with several distinct disease syndromes in wild and domestic animals.

- Avian cholera: it is caused largely by strains of capsular type A, but other capsular types are occasionally incriminated, like type F in turkeys. *P. multocida* will colonize the mucosa of the upper respiratory tract and spread to the air sacs and lungs. It also can enter the circulation directly from the mucosa. The clinical course ranges from a few hours to several days. Morbidity and mortality vary with the virulence of the strain involved (Wilkie et al., 2012).
- Hemorrhagic septicemia: it affects ungulates mostly. It is a systemic disease caused by serogroup B in Asia and Europe, and by serogroup E in Africa. These strains can be isolated from tonsils of healthy animals that can just carry and shed without getting sick, or may develop fulminating hemorrhagic septicemia. Bacteria multiply in peritonsillar soft tissue and will be carried by macrophages to local lymph nodes from where they will spread. Mortality rate is close to 100% without prompt antibiotic treatment (Wilkie et al., 2012).
- Atrophic rhinitis: it affects domesticated dogs and housed rabbits, mostly. It is associated with a dermonecrotxin (PMT: *Pasteurella multocida* toxin), which is produced by capsular type D mostly, but other serogroups may produce it as well. After bacteria colonize the upper respiratory tract mucosa, without the necessity of invasion, it will produce PMT. This toxin will cause osteopaenia and destruction of the local bones (Wilkie et al., 2012).

In humans, opportunistic infections of soft tissue are relatively common. Severe infections can occur in previously healthy individuals. However, immunocompromised host are at particular risk (Wilkie et al., 2012; Weber and Kaplan, 2019).

Human infections with *P. multocida* can be divided into three categories:

1. Local infection after animal bites or scratches. This includes cellulitis, abscesses, necrotizing soft tissue infection, septic arthritis and osteomyelitis.
 - Soft tissue infections usually occur after cat bites or scratches, or dog bites, but also can occur after cat or dog licks of damaged skin. The incubation period for bite wound infections with *P. multocida* is usually less than 24 h, and symptoms often progress rapidly. The most common symptoms include wound site swelling, erythema, tenderness and discharge, but fever, chills and lymphadenopathy may be present as well. Most common complications include abscesses, osteomyelitis, tenosynovitis and septic arthritis (Mogilner et al., 2019).
 - Bone and joint infections occur after a cat or dog bite distal to the involve joint. Most commonly involves a single joint, usually the knee, with a predilection for prosthetic joints or joints previously damaged by another disease (Weber and Kaplan, 2019).

2. Respiratory infections. They usually occur in patients with underlying lung disease (COPD, bronchitis, ...). Includes glossitis, pharyngitis, sinusitis, otitis media, tracheobronchitis, pneumonia, empyema and lung abscess. Pneumonia is the most common respiratory infection caused by *P. multocida*. The clinical course is nonspecific and common symptoms include fever, malaise, dyspnea and chest pain (Weber and Kaplan, 2019).
3. Systematic infections. Often unrelated to animal bites. Include meningitis, intraabdominal infection (peritonitis and appendicitis), endocarditis or ocular infection. Sepsis and septic shock present with purpura fulminans (Weber and Kaplan, 2019).

Diagnosis

Collection and transport of specimens

Specimens from skin and mucosal infections should be collected with a swab and placed into transport media. Specimens from joint infection should be collected into an empty, sterile container, as well as respiratory tract samples, such sputum (Jorgensen et al., 2015).

Samples must be delivered to the laboratory within 2 h. If the deliver to the laboratory will be delayed, samples must be keep refrigerated (Jorgensen et al., 2015).

Direct detection in specimens

For direct detection, Gram staining can be performed on the specimens. *Pasteurella* spp. are small, Gram-negative rods or cocci that may appear singly, in pairs or in short chains. Bipolar staining is frequent (Jorgensen et al., 2015).

Culture isolation and identification

Pasteurella spp. grows well on sheep blood agar and does not require hemin nor CO₂, so it will grow on media without blood. The majority of the species are oxidase, catalase and indole positive; urease negative (except *P. dagmatis*) and they do not grow on MacConkey agar. For separation of the three subspecies of *P. multocida* sorbitol/dulcitol fermentation must be performed (Jorgensen et al., 2015) (Table 3):

Antibiotic susceptibility and treatment

The European Committee on Antimicrobial Susceptibility Testing (EUCAST) has published breakpoints for antimicrobial dilution and disk susceptibility testing. According to their guidelines, broth microdilution testing should be performed on Mueller-Hinton broth +5% lysed horse blood and 20 mg/L β-NAD (MH-F broth); and for disk diffusion method, Mueller-Hinton agar +5% defibrinated horse blood and 20 mg/L β-NAD (MH-F) should be used. In both cases the incubation must be at 35 ± 1 °C for 18 ± 2 h. For disk diffusion method, a 5% CO₂ enriched atmosphere is preferable (The European Committee on Antimicrobial Susceptibility Testing. Breakpoint tables for interpretation of MICs and zone diameters, version 11.0, 2021, available at https://www.eucast.org/clinical_breakpoints/).

Pasteurella spp. are usually susceptible to penicillins, third-generation cephalosporins, fluoroquinolones and trimethoprim-sulfamethoxazole. Recommendations on antibiotic therapy are based on experience. For monomicrobial infections, penicillin is the drug of choice, although rare beta-lactamase-producing strains have been isolated. It is usually resistant to clindamycin, erythromycin and aminoglycosides. Trimethoprim-sulfamethoxazole may be used in patients with allergy to penicillin. Local infections are usually treated for 10–14 days. Bone and joint infections require longer duration of treatment, around 4–6 weeks (Mogilner et al., 2019; Weber and Kaplan, 2019).

Table 3 *Pasteurella multocida* subspecies separation based on sugar fermentation.

<i>P. multocida</i> subspecies	Sorbitol fermentation	Dulcitol fermentation
<i>multocida</i>	+	–
<i>septica</i>	–	–
<i>gallicida</i>	–	+

+, positive; –, negative (Jorgensen et al., 2015).

Campylobacter

Introduction

Campylobacter spp., and particularly *C. jejuni*, is one of the most frequent zoonotic pathogens foodborne and its incidence is increasing in recent years throughout the world (Elhadidy et al., 2018).

It is found commensally in the gastrointestinal tract of wild and domestic animals. Transmission to humans is by the fecal-oral route through the ingestion of undercooked food (especially poultry), unpasteurized milk or contaminated water (Little et al., 2010).

The symptoms that it mainly produces are self-limited diarrhea but can cause severe dysentery and systemic manifestations, especially in immunosuppressed patients, including post infectious complications such as Guillain-Barré syndrome (Elhadidy et al., 2018).

In recent years, an increase in strains resistant to several selected antibiotics of choice has been observed, especially to fluoroquinolones, which highlights the importance of preventing this increasingly frequent frequency (Elhadidy et al., 2020).

Epidemiology

Campylobacter spp. is one of the leading causes of foodborne illness, causing acute bacterial enteritis worldwide. The first infection recognized by *Campylobacter* was at the beginning of the 20th century, where a microorganism with a curved morphology that caused abortions in cattle was observed, first being called *Vibrio fetus* and in the 1970s reclassified as *Campylobacter fetus*. But it was not until the 1980s that its importance as a human pathogen was highlighted thanks to the development of selective media for its isolation (Costa and Iraola, 2019).

It is the most frequent foodborne illness in Europe since 2005 and the second cause in the United States, where the main cause is *Salmonella* spp. (Facciola et al., 2017). The main food source for *Campylobacter* infection is the consumption of undercooked poultry (mainly liver pate) or other cross-contaminated foods, on the farm or during cooking in the kitchen (Little et al., 2010). To a lesser extent, infection can occur through the consumption of unpasteurized milk or contaminated water with excrements of infected animals, since it is capable of surviving on these foods at 4 °C for several weeks. To eliminate it effectively, the liver must be cooked at high temperatures, the water disinfected with chlorine and the milk pasteurized (Hope et al., 2014).

Campylobacteriosis is a worldwide zoonosis found as a commensal in the gastrointestinal tract of domestic or wild cattle. The reservoir of *C. jejuni* is varied, with poultry being the main source of infection. *C. coli* are isolated mainly from pigs, *C. upsaliensis* from dogs and cats, and *C. fetus* from sheep, cattle, poultry, pigs and reptiles (Labarca et al., 2002).

Diarrhea affects all age groups but with a higher incidence in the first 5 years of life according to a study carried out in the United States. In children under 5 years of age *Campylobacter* was the second cause of diarrhea after non-typhoid *Salmonella* (Scallan et al., 2013). According to a cohort study, this incidence is higher in the first 2 years of life, placing *Campylobacter* spp. among the six most frequent microorganisms that cause diarrhea, along with rotavirus, norovirus, astrovirus, *Shigella* spp. and *Cryptosporidium* spp. (Platts-Mills et al., 2015).

Campylobacter infections are usually sporadic and are more frequent in summer and autumn and may be due to increased air temperature and the presence of a greater number of flies, considered possible vectors of transmission (Nichols, 2005).

There are epidemiological differences in different countries, since campylobacteriosis is endemic in developing countries, affecting up to 40% of children with or without symptoms (Buss et al., 2019). In these countries, person-to-person transmission seems to be higher than in developed countries, since there is greater contact with animal vectors of the infection, as occurs in rural areas of developed countries where the incidence is also higher (Shah et al., 2009).

Due to the high incidence of diseases caused by *Campylobacter*, its low infectious dose in humans ($5-8 \times 10^2$ cells/mL) and its potentially serious sequelae. It should be considered as a significant risk to public health (Moore et al., 2005).

Microbiology

Campylobacter spp. belongs to the Campylobacteraceae family and is composed of 32 species and 9 subspecies (Costa and Iraola, 2019). *C. jejuni* and *C. coli* are the species that most frequently cause pathology in humans and represent 90% of infections, and less frequently *C. fetus* (Elhadidy et al., 2020).

They are Gram-negative rods, curved (comma-shaped) and mobile, due to the presence of one or two polar flagella. They are small in size, 0.5–5 µm long and 0.2–0.5 µm wide. They are non-spore forming; they react positively to oxidase and variably to catalase. More than 90 different serotypes have been described based on somatic antigens (O) and thermolabile antigens (flagellar and capsular).

It grows easily in microaerophilic conditions (5–10% oxygen) and its optimal growth temperature is wide, from 25 °C to 42 °C. Although they tend to grow well at 37 °C, incubation at 42 °C allows to specifically recovering those thermophilic species responsible for most cases of enteritis, such as *C. jejuni* and *C. coli*. Another characteristic that differentiates *C. jejuni* from the rest of the species of the genus is the hydrolysis capacity of hippurate, although 5–10% of the strains do not present this characteristic (Snelling et al., 2005).

Pathogenesis

Campylobacter is able to invade the gastrointestinal epithelial barrier due to the presence of multiple adhesins responsible for binding to fibronectin and the production of the cytotoxic strain toxin. This toxin has DNase activity that causes DNA damage and is responsible for invading and altering the density of endocrine cells in the colon and even reaching the rectum, which can lead to post infectious irritable bowel syndrome (El-Salhy et al., 2013). Another important virulence factor that allows it to cross this epithelial barrier is its motility, due to the presence of flagella, and its characteristic corkscrew shape (Fouts et al., 2005). These virulence factors along with a low infective dose are responsible for the clinical symptoms.

In cases where there is a prolonged excretion of *Campylobacter*, as in immunosuppressed patients, there is an alteration of the integrity of the epithelium that leads to permanent damage to the mucosa and subsequent complications (El-Salhy et al., 2013).

The main virulence factor of *C. fetus*, responsible for systemic manifestations, is the presence of a protein in its surface layer that acts as a capsule. This prevents their phagocytosis and facilitates extra intestinal spread, mainly in immunosuppressed patients (Dworkin and Blaser, 1997).

Clinical manifestations

The genus *Campylobacter* most frequently produces intestinal diseases, especially *C. jejuni*, followed by *C. coli*. It can also produce extra intestinal manifestations, especially in immunosuppressed patients, produced in most cases by *C. fetus*.

Campylobacter jejuni infection

The main manifestation produced by *C. jejuni* is acute enteritis. It mainly affects children under 5 years of age and young adults, although it can occur at any age. The incubation period is 2–5 days, in which the patient has watery diarrhea, abdominal pain and/or fever, most of the time being a mild and self-limited condition that resolves in a week. *Campylobacter* is one of the main causes of traveler's diarrhea, especially in Southeast Asia. In people with previous pathologies or in immunosuppressed people it can produce a more serious picture of dysentery, with fever and blood in the stool, and even later complications (Ternhag et al., 2007).

Extraintestinal manifestations occur exceptionally and more frequently in immunosuppressed patients, especially with immunoglobulin or HIV deficiencies, where infections are more severe, prolonged and recurrent. Bacteremia is observed in less than 1% of patients, being normally transient or with good evolution in immunocompetent patients (Nielsen et al., 2010).

It has been related, mainly in developing countries, with malnutrition in young children, even asymptomatic, since in children under 2 years old it usually produces dysentery. This highlights the importance of its early detection and subsequent treatment (Lee et al., 2013a,b).

The complications that can occur, especially in immunosuppressed patients, are:

- Guillain-Barré syndrome (GBS): it is an autoimmune disease of the peripheral nerves that occurs because *C. jejuni* lipooligosaccharides can induce a cross-reactive immune response with nerve gangliosides due to molecular mimicry. 20–50% of GBS cases are preceded by a *C. jejuni* infection (Heikema et al., 2013).
- Post-infectious irritable bowel syndrome: this condition is characterized by intestinal disorders and chronic abdominal pain that can persist up to 10 years after the episode of acute enteritis. It can be caused by *Campylobacter* or other enteropathogens (Dai et al., 2020).
- Reactive arthritis: it is a sterile joint inflammation that can occur after a gastrointestinal infection, being *C. jejuni* the most common bacterial enteropathogen. Its association with the presence of HLA-B27 histocompatibility antigens is not yet clear (Hannu et al., 2004).

Campylobacter fetus infection

Infection with *C. fetus* is rare but can cause serious symptoms due to its ability to spread extraintestinally, especially in immunosuppressed patients.

C. fetus can produce local symptoms of gastrointestinal involvement, although much less frequently than *C. jejuni* and most of the time it is responsible for invasive conditions such as bacteremia, pneumonia and meningoenitis. It seems to have a predilection for endovascular tissue, as it can lead to serious conditions such as endocarditis or fungal aneurysms (Haruyama et al., 2011).

It mainly affects adults with previous diseases or immunosuppressed; and in patients with immunoglobulin deficiencies it can cause recurrent infections difficult to treat, such as persistent bacteremia and other local symptoms (septic arthritis, cellulitis or osteomyelitis) (Yamagami et al., 2014).

Infection with other *Campylobacter* species

The clinical manifestations of *C. coli* are similar to those produced by *C. jejuni*, although it appears to be somewhat milder.

C. upsaliensis, like *C. fetus*, produces diarrhea in immunocompetent patients and bacteremia in immunosuppressed patients, although it is believed to be underdiagnosed since it cannot be detected with the incubation conditions of the stool culture media used for the diagnosis of the rest of *Campylobacter*, being necessary its incubation at 37 °C. It is believed that it is transmitted through contact with feces of domestic pets or food contaminated with them (Nakamura et al., 2015).

Diagnosis

The microbiological diagnosis of diarrhea is not usually necessary in most patients because it is often a mild and self-limited condition. On the opposite, in the case of bloody stools, fever or prolonged diarrhea, a stool sample should be taken for culture and subsequent identification of the most frequent pathogens that cause diarrhea, among which is *Campylobacter*.

For the identification of thermophilic species, which are responsible for acute diarrhea, selective culture media with blood and antibiotics (Skirrow medium, Butzler agar and Campy-BAP medium) are used, which inhibit the growth of other species of *Campylobacter*. In cases in which diarrhea due to *C. fetus* or other atypical species is suspected, the plates should be incubated at 37 °C. It can also be isolated from blood cultures, although it may take up to 14 days to grow, so if it does not exist clinical suspicion

will not be possible a correct identification. The drawback of cultivation is that it is a slow method, it takes 48–72 h to grow and requires special media for its growth. It also has lower sensitivity than molecular methods, approximately 70%, which may be due to the loss of viability when kept refrigerated until culture or to the low bacterial load of some samples (Buss et al., 2019).

The use of mass spectrometry (MALDI-TOF) allows an excellent and rapid identification of *Campylobacter* species and is used as confirmation against a colony that grows under microaerophilic conditions and that presents the characteristic morphology in the Gram stain.

In recent years, rapid diagnostic techniques such as immunochromatography tests are being used that allow a diagnosis in less than 30 min with good sensitivity and specificity. They are very useful to establish an adequate treatment earlier and to detect cases with a low bacterial load that cannot be recovered by culture, but they do not detect all pathogenic *Campylobacter* species and are less sensitive than culture (Franco et al., 2021; Balsalobre-Arenas and Alarcón-Cavero, 2017).

Molecular biology techniques increasingly used in laboratories are more sensitive and faster than culture and are usually part of a panel of enteropathogens that allows the screening of the main gastrointestinal infections in a single step. Their main drawback is that they need specific automation, trained personnel, and they must be interpreted with caution as they can detect non-viable organisms. These techniques have the disadvantage that they do not allow us to know the resistance to antibiotics, this being fundamental due to its current increase, so it is always necessary to also perform the culture considered the gold standard technique for the identification of *Campylobacter* infection (Poppert et al., 2008).

Treatment

Most of the patients present a mild and self-limited condition, being only necessary support treatment for the replacement of fluids and electrolytes and thus avoid dehydration (Snelling et al., 2005).

The use of antibiotics for the treatment of diarrhea due to *Campylobacter* is only beneficial in those patients at risk such as the immunosuppressed, the extreme ages of life, severe diarrhea (more than eight stools a day) or of prolonged evolution. In these situations, complications and systemic manifestations can also occur, so the use of antibiotics in these patients reduces the elimination of bacteria through the feces and the duration of the symptoms, especially if they are administered early (González-Abad and Alonso-Sanz, 2013). The difficulty lies in knowing in which patients should be administered antibiotics and in which not, since the ideal is that these are given early but in most cases it will not be necessary because it is a self-limiting disease, which leads to an increase in resistors (Ternhag et al., 2007).

The antibiotics of choice include macrolides, fluoroquinolones and aminoglycosides, but fluoroquinolone-resistant strains of *C. jejuni* have emerged since the 1990s. This is related to its indiscriminate use and greater administration at the veterinary level, mainly in poultry (Dai et al., 2020). These resistances are largely due to mutations in the topoisomerase gene (*gyrA*), which confers high-level resistance to nalidixic acid and ciprofloxacin (Elhadidy et al., 2018). Several studies report levels of resistance to ciprofloxacin higher than 80% in countries such as Spain and Thailand, and this resistance is spreading to other parts of the world, which is why its use as an empirical treatment is discouraged (Mason et al., 2017).

In countries with a high prevalence of resistance to fluoroquinolones, the first line treatment is macrolides, although resistance to these drugs is being observed in developing countries due to ribosomal mutations or through the efflux pump. To this day, the incidence of macrolide resistance in Europe and the United States remains low (Dai et al., 2020). Thus, azithromycin is the treatment of choice for travelers, especially to areas of Southeast Asia, since it is also effective against other bacteria that cause traveler's diarrhea (Mason et al., 2017).

For the treatment of systemic infection, the antibiotics of choice are intravenous carbapenems and aminoglycosides for at least 2 weeks. It is not advisable to administer fluoroquinolones due to the increase in resistance observed or 3rd generation cephalosporins, since they present resistance of up to 20% (Yamagami et al., 2014).

Furthermore, it has been observed in recent studies that patients infected by these resistant strains present more severe and longer-lasting symptoms, a fact that highlights the importance of continuing to study the molecular mechanisms responsible for resistance in *Campylobacter* (Elhadidy et al., 2020). For these cases of multidrug resistant *Campylobacter*, the association of fosfomicin-tromethamine is proposed as an alternative therapy with good results (Aguilar-Company et al., 2016).

Prevention

There are regulations in the food sector aimed at the prevention of food-borne illnesses, including *Campylobacter* infection. These controls are based on improving slaughter hygiene, especially poultry, and reducing microbial contamination by establishing limit values for microorganisms such as *Campylobacter*.

The population should also be informed of the measures to be taken when handling food for consumption, including thorough cooking of the meat and good cleaning of both the kitchen equipment and the handler's hands.

Currently, the development of an effective vaccine for *Campylobacter* infection is still in the research phase, this difficulty is due to the fact that it presents a great antigenic diversity (Kreling et al., 2020).

Helicobacter

Introduction

Helicobacter pylori (*H. pylori*) is a highly mobile, curved Gram-negative rod that colonizes the human gastroduodenal mucosa of approximately half the world's population (Gravina et al., 2018). Most people have no symptoms, but their presence is associated with an increased risk of peptic ulcer and gastric carcinoma (Chmiela and Kupcinskas, 2019).

In recent years the prevalence of *H. pylori* is decreasing in developed countries while it remains high in developing countries related to low socioeconomic status.

H. pylori eradication therapy is one of the pillars of the strategy to eliminate gastric cancer and peptic ulcer, but in recent years an increase in antibiotic resistance has been observed, which has resulted in therapeutic failures. Hence the importance of detecting resistance before starting treatment thanks to the use of new diagnostic techniques (Pohl et al., 2019).

Epidemiology

H. pylori is normally acquired during childhood and can last for a lifetime (Eed et al., 2019). In developing countries more than 70% of children older than 10 years are carriers. Transmission of the infection occurs by the fecal-oral route, through contaminated food and water; and to a lesser extent it can also be transmitted by oral-oral route since it has been isolated in dental plaque and saliva (Gravina et al., 2018).

The global prevalence of *H. pylori* varies between different regions and countries, being highest in Africa, followed by Latin America and Asia; and it is lowest in North America and Oceania. *H. pylori* infect approximately half of the world's population.

The prevalence of *H. pylori* colonization varies according to the socioeconomic development of the country and according to age. Since the 21st century, the incidence has been decreasing in developed countries due to improvements in sanitation, access to drinking water... and even within the same country there are differences between regions, being greater in the most disadvantaged (Hooi et al., 2017).

Microbiology

Within the genus *Helicobacter* there are several species that cause pathology in humans, such as *H. fennelliae* and *H. cinaedi*, although the most important species is *H. pylori* and it is the one that we will talk about in this topic.

Due to its typical S-shaped morphology, this microorganism was published in the 1980s, known as *Campylobacter pylori* or *pyloridis* and later classified as *H. pylori* (Serena et al., 2018).

H. pylori are a small, microaerophilic, curved (corkscrew-shaped) Gram-negative rod (0.5–1.0 µm wide and 2.5–4 µm long). It is mobile thanks to the presence of 4–8 polar flagella that allow it to reach the protective mucus layer of the stomach and are covered by a lipid structure that is believed to be responsible for its protection from the acidic environment of the stomach. Its reaction to oxidase and catalase is positive, and its biochemical characteristics include the presence of a urease with a more powerful action than that of other bacteria (Frydman et al., 2015).

Pathogenesis

H. pylori are able to survive in the acidic environment of the stomach thanks to its curved shape and the presence of flagella that allow it to move through the mucous layer of the stomach. In addition, the activity of urease allows it to neutralize stomach acid by converting urea from gastric juices into ammonia and carbon dioxide (Serena et al., 2018).

H. pylori colonize the gastric mucosa thanks to the presence of adhesins that interact with the mucin and produce an increase in it, which facilitates bacterial adherence. *H. pylori* activates gastric epithelial cells that produce pro-inflammatory cytokines and activate polymorphonuclear and mononuclear cells, triggering an inflammatory response and a decrease in mucus in the epithelial glands (Tham et al., 2001).

Virulence factors include a cytotoxin-associated protein (CagA) produced by some strains of *H. pylori*, which has demonstrated its oncogenic capacity by producing a massive vacuolation of gastric epithelial cells, playing a key role in the development of gastric cancer (Serena et al., 2018). Another pore-forming protein (VacA) is also produced whose toxicity is increased by the ammonia produced by urease (Chmiela and Kupcinskas, 2019).

H. pylori produces an increase in gastrin-producing cells and acid-producing parietal cells, this being responsible for the long-term chronic active gastritis that can progress to premalignant stages of atrophic gastritis, intestinal metaplasia and dysplasia up to get to gastric cancer (Lu and Li, 2014).

Clinical manifestations

The presence of *H. pylori* is related to various gastric pathologies, although most of the time it is asymptomatic, being the most frequent cause of chronic gastritis and peptic ulcer, and less frequently it can produce systemic manifestations. Its presence has also been observed to protect against other diseases (Vaezi et al., 2000).

Gastritis

Exposure to *H. pylori* can cause acute gastrointestinal symptoms or be asymptomatic. Usually, this colonization will remain for years and in many cases without symptoms and in some people it will cause symptoms of gastritis or non-ulcer dyspepsia, being responsible for 10% of these cases.

Duodenal ulcer

H. pylori is found in more than 90% of patients with idiopathic duodenal ulcer, which is one not related to the use of non-steroidal anti-inflammatory drugs or Zollinger-Elison syndrome. The risk of developing an ulcer is even higher in patients with CagA-producing strains of *H. pylori*.

A causal association between *H. pylori* and duodenal ulcer formation has not been demonstrated, although a reduction in duodenal ulcer recurrence rates has been observed when *H. pylori* eradication therapy is administered in conjunction with antacids. In contrast, recent studies have shown that the incidence of reflux esophagitis increases after *H. pylori* eradication, demonstrating that this eradication therapy has both benefits and harms (Lee et al., 2013a,b).

Gastric ulcer

The proportion of patients with gastric ulcers colonized by *H. pylori* is lower than in the case of duodenal ulcers (50–80%), due to the more frequent association of gastric ulcer with the use of non-steroidal anti-inflammatory drugs. The presence of gastric ulcers, especially in the area of the body of the stomach, is associated with the development of diffuse gastric cancer. This is because *H. pylori* are able to decrease gastric mucosal bicarbonate secretion by reducing two cellular bicarbonate transporters, thereby removing its barrier against stomach acid damage. *H. pylori* eradication therapy in these patients is associated with the non-development of cancer (Chmiela and Kupcinskas, 2019).

Gastric cancer

Gastric cancer is the third leading cause of cancer death and the fourth most common cancer worldwide. About half of gastric cancers are diagnosed in Asia, mainly China, and it is more common in men.

In approximately 89% of cases of gastric cancer, not heart cancer, *H. pylori* is involved, considered a necessary but not sufficient cause for cancer to develop (Hooi et al., 2017). Among the risk factors for developing gastric cancer is host, environmental and bacterial factors, such as the expression of the CagA protein. It is also related to dietary factors, such as a diet low in fruits and vegetables and rich in salt (Ang and Fock, 2014).

Gastric cancer of the intestinal type and diffuse type has been shown to be closely related to the presence of intestinal metaplasia and atrophic gastritis, and these are in turn associated with persistent *H. pylori* infection. Furthermore, worldwide, a correlation is observed between areas with high rates of *H. pylori* infection and high rates of cancer of the antrum and the gastric body (Lee et al., 2016).

H. pylori eradication therapy has been shown to stop the progression of gastric mucosal injury and restore the microbiome, resulting in a decrease in the incidence of gastric cancer. This reduction occurs when there are premalignant lesions, such as atrophic gastritis, but not if there is already irreversible intestinal metaplasia (Lee et al., 2013a,b). This protective effect is greater in those with a higher risk of initial gastric cancer, so *H. pylori* eradication therapy is considered the main gastric cancer prevention strategy (Lee et al., 2016).

MALT type gastric lymphoma

Most gastric lymphomas originate from B lymphocytes and are called mucosa-associated lymphoid tissue (MALT) lymphomas. These lymphomas are associated with chronic *H. pylori* infection and are believed to be due to antigenic stimulation and subsequent polyclonal lymphoid response. Complete remissions of these lymphomas have been described after *H. pylori* eradication therapy in both immunocompetent and immunosuppressed patients (Verduzco-Rodriguez et al., 2017).

Extra-digestive manifestations

H. pylori has also been linked to extradigestive diseases including vitamin deficiencies, such as vitamin B12, childhood asthma and other related diseases, and hematological diseases such as idiopathic thrombocytopenic purpura (ITP). In recent decades, an association has been observed between the presence of *H. pylori* and ITP. The exact cause is not known but it appears to be because the CagA protein stimulates anti-CagA antibodies that are cross-reactive with platelet surface antigens, leading to platelet aggregation. Currently, patients with ITP are evaluated for the presence of *H. pylori* and if it is positive, eradication therapy is recommended in highly endemic areas (Frydman et al., 2015).

In recent years, an increase has been observed in a series of pathologies related to the decrease in colonization by *H. pylori* due to eradication therapy. These include pathologies of the esophagus, such as gastroesophageal reflux disease, Barrett's esophagus and

adenocarcinoma of the esophagus. These diseases have increased since *H. pylori* eradication therapy has been introduced. An inverse correlation has been observed between the presence of CagA positive *H. pylori* strains and esophageal diseases, so that these strains could act as a protective factor against these diseases due to the decrease in stomach acid, among other mechanisms (Vaezi et al., 2000).

Diagnosis

For the diagnosis of *H. pylori* infection, two types of techniques can be performed, invasive or non-invasive, with their respective advantages, disadvantages and limitations. Nowadays, the diagnosis should only be made in symptomatic cases, and it is not routinely indicated (Pohl et al., 2019).

Invasive techniques

Invasive testing is performed using endoscopically obtained gastric biopsy specimens, including histology, culture, rapid urease test and molecular techniques. Endoscopy has the advantage that other lesions such as masses and strictures can also be evaluated. Due to the irregular distribution of *H. pylori* in the stomach, it is recommended to take two samples from the antrum and another two from the greater curvature of the gastric body, since in this way fewer false negative results are obtained.

Histology

Histology was the first method used for the diagnosis of *H. pylori* infection. Different stains are used, such as Giemsa or silver staining, which together with the presence of bacteria with a typical morphology and the inflammatory reaction of the tissue, the diagnosis is made. It presents a series of limitations that reduce its precision, such as the size and number of biopsies, the experience of the pathologist, the staining methods or the use of proton pump inhibitors (it is recommended not to consume these drugs 2 weeks before endoscopy to avoid false negative results). In recent years, specificity has been improved with non-morphology-based techniques, such as fluorescent nucleic peptide in situ hybridization (PNA-FISH). It is also a useful method to detect clarithromycin resistance, although it requires experienced personnel and a fluorescence microscope (Wang et al., 2015).

Culture

The samples are cultured in selective media, such as Skirrow medium or Columbia Agar base broth or Brain Heart Infusion (BHI) supplemented with blood agar, for 5–7 days at 37 °C in a humid microaerobic atmosphere (5% oxygen). The growing colonies are confirmed with a Gram stain to observe their characteristic shape and the positivity of the oxidase, catalase and urease tests. Culture has the advantage that it allows the study of sensitivity to antibiotics, which is very important due to the current increase in resistance, but has the disadvantage that it is a slow method and requires special media and conditions, as it is a bacterium demanding.

Rapid urease test

This test is performed by inoculating the biopsy in urea broth and observing the color changes to pink after a few minutes, due to the activity of its powerful urease (Balsalobre-Arenas and Alarcón-Cavero, 2017). It has a sensitivity of 60% that increases to more than 90% after 24 h of incubation. It has the advantage of being quick and easy to perform, but the disadvantage of low sensitivity if there is a low bacterial concentration, since a minimum of 10^4 microorganisms is needed per biopsy piece (Patel et al., 2014).

Molecular methods

The real-time polymerase chain reaction (PCR) is used both for the identification of the bacteria and for the detection of mutations related to antibiotic resistance in samples such as gastric biopsy, gastric juice, feces or saliva. Resistance to macrolides such as clarithromycin (23S rRNA gene), fluoroquinolones (gyrA gene), tetracyclines (16S rRNA gene), rifabutin (rpoB gene), and amoxicillin (pbp-1a gene) can be detected. These techniques have the advantage of being faster and more sensitive than culture, and they are also capable of detecting heterogeneous resistance.

Non-invasive techniques

Serology

There are several techniques that detect antibodies anti-*H. pylori* IgG in the patient's serum, but its main limitation is that it does not differentiate between active and past infection. It is a useful test in epidemiological studies and in those situations with a low bacterial load in the stomach, where the rest of the tests will show a decrease in sensitivity.

Carbon-13 (13C) urea breath test

It consists of administering a food with ^{13}C or ^{14}C -labeled urea and at the hour the amount of CO_2 marked in the breath is measured. This CO_2 is released when urea is hydrolyzed by the *H. pylori* enzyme urease (Balsalobre-Arenas and Alarcón-Cavero, 2017). It has a sensitivity and specificity greater than 90%. It is used to evaluate the efficacy of *H. pylori* eradication therapy and false positives may occur as there are other urease-producing bacteria in the stomach (Patel et al., 2014).

Stool antigen test

It is a test that is usually used for the initial diagnosis of *H. pylori* infection in symptomatic patients, being very common in Microbiology laboratories. It is also used for monitoring treatment (4 weeks later) and for epidemiological studies. False negatives can occur with the presence of some preservatives in the stool such as formaldehyde (Wang et al., 2015; Balsalobre-Arenas and Alarcón-Cavero, 2017).

Treatment

H. pylori eradication therapy is one of the pillars for the prevention of peptic ulcer and gastric cancer. Today the World Health Organization (WHO) has established that all *H. pylori* infected patients should be treated regardless of whether or not they present symptoms, since it is the best strategy to prevent gastric cancer (Serena et al., 2018). If the treatment is carried out correctly, it has a high efficacy rate with a very low probability of reinfection (2%), but its efficacy is decreasing due to the increase in resistance to 1st-line antibiotics (Pohl et al., 2019). The treatment consists of a combination of antibiotic and antisecretory agents, like as proton pump inhibitors (PPIs), which increase the gastric pH necessary for the bactericidal effect of antibiotics. The antibiotics included in eradication therapy are amoxicillin, clarithromycin, fluoroquinolones, metronidazole and tetracycline. For the therapy to be effective, a combination of two or more antibiotics are required due to increased resistance, known as standard triple therapy that includes two antibiotics (clarithromycin and amoxicillin/metronidazole) and a PPI. This therapy has been considered 1st line but in recent years an eradication rate of less than 80% has been observed in several areas due to the increase in antibiotic resistance, which makes it necessary to use quadruple or bismuth salt therapies for 14 days, with cure rates greater than 90% (Yan et al., 2014).

Genes for resistance to clarithromycin, tetracycline, fluoroquinolones and metronidazole have been described. (Eed et al., 2019). The most frequent resistance is to clarithromycin and is currently increasing, with an overall rate of almost 20% in Europe with variations between different countries, and can reach up to 50% in China. Resistance to metronidazole is less common but it also reduces the effectiveness of triple therapy and is increasing in recent years. Due to this, an alternative therapy must be evaluated in regions with high rates of resistance to 1st-line antibiotics and the ideal is to carry out sensitivity studies before administering the treatment to avoid failure (Pohl et al., 2019). Because culture is a slow and demanding method, faster techniques are needed and several commercial kits are currently available that detect, directly from the biopsy, the presence of *H. pylori* and the main resistance mutations to clarithromycin and fluoroquinolones with very good sensitivity and specificity (Balsalobre-Arenas and Alarcón-Cavero, 2017).

In countries with a low rate of resistance to clarithromycin (<15%), triple therapy is administered based on the association of a PPI, clarithromycin and metronidazole or amoxicillin; or quadruple bismuth therapy. In countries with a high rate of resistance to clarithromycin (>15%) and low resistance to metronidazole, triple therapy with a PPI, amoxicillin and metronidazole can be administered (Pohl et al., 2019). For those patients who present resistance to the 1st line, fluoroquinolones can be used as 2nd line therapy, although resistance to them is also increasing (Eed et al., 2019).

There is currently no effective vaccine for *H. pylori* infection. More studies are needed and research is continuing (Pohl et al., 2019).

Introduction

Haemophilus, Bordetella and Bartonella are pleomorphic gram-negative bacteria with fastidious growth, which can produce a wide variety of clinical symptoms. This chapter briefly summarizes and updates the microbiological characteristics, epidemiology and laboratory diagnosis of these fastidious bacteria and describes the pathophysiology and treatments caused by these microbes (Fig. 1).

Haemophilus

The genus Haemophilus includes gram-negative, facultative anaerobic, pleomorphic bacteria found in the mucous membranes of humans. They are classified within the family Pasteurellaceae, as are the genera Actinobacillus, Aggregatibacter and Pasteurella. The number of Haemophilus species includes a long list of pathogenic and non-pathogenic bacteria, but 6 species affecting humans are particularly relevant: *H. aegyptius*, *H. ducreyi*, *H. haemolyticus*, *H. paraemolyticus*, *H. parainfluenzae* and *H. influenzae*, being *H. influenzae* the most commonly associated with human disease.

Microbiology

The genus Haemophilus consists of small gram-negative, immotile, aerobic or facultative anaerobic bacilli or coccobacilli with fastidious growth requirements. For their development they require the addition of growth factors present in the blood, especially hemin (called factor X) and nicotinamide dinucleotide (NAD), also called factor V. Because of their requirement of factors, they are demanding bacteria and grow only in specific media (chocolate agar or supplemented chocolate agar) or with an exogenous source of essential nutrients (satellitism around a *Staphylococcus aureus* streak or supply of specific nutrients). Optimal growth is obtained by incubating the plates in a 5% CO₂ atmosphere at 35–37 °C (Kilian, 1976, 2009).

The requirements of factors X and V, the porphyrin test and the use of sugars are the most important properties for the classification of the genus Haemophilus (Table 1).

H. influenzae strains may produce one of six distinct capsular polysaccharides or may be nonencapsulated. The capsule consists of repeating units of one of six different disaccharides, which provides the basis for differentiating six distinct antigenic serotypes from

Fig. 1 Phylogenetic distance and most frequent species of different genera of bacteria described in this article.

Table 1 Growth requirements of the most common *Haemophilus* species.

<i>H. parahaemolyticus</i>	–	+	+

a to f (Hia-Hif) (Lâm et al., 2011). *H. influenzae* strains that are not encapsulated are commonly referred to as nontypeable *H. influenzae* (NTHI). Assignment of the different serotypes can be done by slide agglutination or by nucleic acid amplification techniques (NAATs); agglutination on slides leads to a high discordance rate compared to polymerase chain reaction (PCR)-based methods (Nørskov-Lauritsen, 2014). Of all the serotypes, *H. influenzae* type b (Hib) stands out, since it contains a polysaccharide antiphagocytic capsule, formed by ribose, ribitol and phosphate (polyribosyl ribitol phosphate; 5-D-ribitol-(1 → 1)-β-D-ribose-3-phosphate; PRP) which constitutes its main virulence factor.

Epidemiology

Haemophilus species occur in almost all individuals colonizing mainly the nasopharyngeal and genital mucous membranes. *H. parainfluenzae* and unencapsulated *H. influenzae* are predominantly found in the mouth and upper respiratory tract (Kuklinska and Kilian, 1984). Carriage of *H. influenzae* Hib, associated with severe and invasive infections, has decreased from up to 5–0.05% since introduction of the Hib conjugate vaccine in the 1980s. By contrast, non-typeable *H. influenzae* strains together with strains of *H. parainfluenzae* still represent a major portion of the cultured bacterial microbiota of the upper respiratory tract of healthy humans (Morris et al., 2008).

With regard to the incubation period for *H. influenzae* infection, it is still a question poorly understood. Preceding viral infections, Hib capsule, and host-deficient antibody responses may lead to increasing bacterial proliferation, tissue invasion and colonization of inflamed or damaged mucosa. Accession to the bloodstream may further lead to bacterial dissemination to multiple sites and severe disease, including: meninges, subcutaneous sites, joints, pleura and lungs (Agrawal and Murphy, 2011; Nørskov-Lauritsen, 2014).

H. ducreyi infection is mainly prevalent in parts of Africa, being uncommon in Europe and North America. Until 1999, a high rate (>35%) of *H. ducreyi* infections was reported in African countries (published studies in Côte d'Ivoire, Gambia, Kenya, Lesotho, Senegal, South Africa, and Swaziland). However, after 2000, a clear decrease in the proportion of *H. ducreyi* cases was observed as a result of social changes and improved antimicrobial stewardship in these countries. Despite this favorable trend, the CDC (Centers for Disease Control and Prevention) has documented that the disease goes largely unrecognized and underreported, so its true incidence is unknown (González-Beiras et al., 2016).

Clinical manifestations

- Bloodstream infections caused by *H. influenzae* have been nearly eliminated in populations where polysaccharide conjugate vaccine programs have been implemented. However, invasive infections caused by other serotypes and non-typeable strains have increased due to Hib and pneumococcal conjugate vaccines. Therefore, non-Hib *H. influenzae* strains still represent an important cause of community onset bacteremia, particularly for very young infants and patients aged >65 years. Upper respiratory tract appears to be the most important focus and reduced susceptibility to ampicillin, age >90 years and dissemination to central nervous system are factors associated with a poor prognosis (Laupland et al., 2011).
- Meningitis caused by *H. influenzae* type b was the most frequent cause of pediatric meningitis until the vaccine became available. It is caused by blood-borne dissemination of the microorganisms from the nasopharynx. It begins with mild upper respiratory symptoms lasting 3 days, followed by signs and symptoms characteristic of bacterial meningitis. Currently, cases of invasive *Haemophilus* infection have greatly decreased, and are associated with cases of immunosuppression, HIV infection and respiratory disorder. Although rare, there are reported cases of non-type b *H. influenzae* meningitis due to the spread of the vaccine (Fickweiler et al., 2004; Sawardekar, 2017).
- Orbital cellulitis due to *H. influenzae* is an invasive clinical entity that frequently affects children under 36 months. Orbital cellulitis is usually associated with high fever, leukocytosis and blue-purple discoloration of the eye affected areas, in which abscesses may appear. Bacteremia and central nervous system infection with neurological complications may also appear (Sharma et al., 2015).
- Epiglottitis caused by *H. influenzae* type b has considerably decreased its incidence thanks to the conjugate vaccine, as has happened with meningitis. It used to represent a pediatric emergency because affected children presented with pharyngitis, fever and respiratory distress, which rapidly progressed to complete airway obstruction and death. Currently, Hib is no longer the dominant organism causing epiglottitis, being replaced by a variable microbiome of causal pathogens of this entity (Baird et al., 2018).
- Otitis, sinusitis and lower respiratory tract infections. *Haemophilus influenzae* may gain access to different focus of infection by direct contagious spread from its frequent reservoir in the respiratory tract. Conjunctival infection may appear through direct inoculation of the bacteria in the eyes, probably by contact with hands contaminated with respiratory secretions. Previous viral infections and inflammation of the eustachian tubes may favor subsequent infection of the middle ear cavity and maxillary sinuses. Additionally, establishment of infection in the lungs is facilitated by underlying conditions that may affect mucociliary clearance, such as smoking, EPOC, other bacterial infections or other conditions such as cystic fibrosis and bronchiectasis (Murphy, 2003).
- Acute purulent conjunctivitis is associated with *H. aegyptius* (Koch-Weeks bacillus). This pathogen is also the cause of Brazilian purpuric fever (BPF), a fulminant pediatric disease, with a clinical course very similar to meningococcal sepsis (high fever, vomiting, abdominal pain, rapid progression of petechiae and vascular collapse) (Cury et al., 2014).
- Chancroid or soft chancre is a sexually transmitted disease caused by *Haemophilus ducreyi*. A painful ulcer with an erythematous base form on palpation in the genital or perianal region 5–7 days after exposure. It is often accompanied by inguinal lymphadenopathy which may suppurate. Recently, *H. ducreyi* has been identified as a possible cause of chronic skin ulcers on the legs of children and adults living in the Pacific and African regions (Lewis and Mitjà, 2016).

Diagnosis

Diagnosis of the different *Haemophilus* species is made by traditional culture from a wide variety of clinical samples (respiratory samples, ear exudates and urethral exudates, cerebrospinal fluid, synovial fluid, etc.). The culture is highly specific, but may have low sensitivity in those patients who have received antibiotic treatment or in those samples that have not been taken properly. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry allows identification to species level of *Haemophilus* with high sensitivity and specificity, however, MALDI-TOF cannot differentiate between typeable and nontypeable *H. influenzae* and does not permit susceptibility testing (Chen et al., 2017). The diagnosis of *H. influenzae* can also be confirmed by PCR-based assays. The advantages of these tests are based above all on their high sensitivity and specificity, and they can be used in patients who have received antibiotics (Abdeldaim et al., 2009). Currently, there are commercial PCR-based assays that allow the detection of *H. influenzae* directly from clinical specimens (in less than 2 h), saving valuable diagnostic time (e.g., BIOFIRE FILMARRAY® Meningitis/Encephalitis Panel, Curetis Unyvero® P55 /P50, etc.).

Treatment

Treatment for *Haemophilus* infections varies according to severity and location. In severe systemic infections by capsulated *H. influenzae* (meningitis or epiglottitis), early antimicrobial treatment is required, generally with broad-spectrum cephalosporins, ceftriaxone 2 g/12 h or cefotaxime 2 g/4–6 h iv 7–10 days. In cases of meningitis, dexamethasone 0.15 mg/kg/6 h iv 2 days would be added. In less severe infections, such as sinusitis and otitis, they can be treated with oral antibiotics, such as amoxicillin, cefixime, azithromycin or a fluoroquinolone (avoiding its use in children). *H. ducreyi* infections can be treated with single doses of ceftriaxone, azithromycin or ciprofloxacin or with longer regimens with erythromycin.

Both *H. influenzae* and *H. parainfluenzae* can present resistance to ampicillin alone or in association with multiple resistance to other drugs, such as co-trimoxazole, chloramphenicol, tetracyclines and aminoglycosides. The most frequent mechanism of ampicillin resistance is the plasmid production of a β -lactamase type TEM-1 and, more rarely, of the ROB-1 type, both inhibited by clavulanic acid, so that these strains retain their sensitivity to the amoxicillin-clavulanic acid combination and to third-generation cephalosporins (Tristram et al., 2007). In the United States, approximately 25% of *H. influenzae* strains are estimated to produce beta-lactamase (Heilmann et al., 2005). Occasionally there are strains of *H. influenzae* that do not produce beta-lactamase but are nevertheless resistant to amoxicillin and ampicillin due to changes in penicillin binding proteins (PBPs). These strains are designated as "beta-lactamase negative, ampicillin resistant" or BLNRA strains and are prevalent in Asia (Han et al., 2019). Most BLNRA strains, like beta-lactamase positive strains, maintain susceptibility to third generation cephalosporins (Ohno et al., 2007).

Resistance to third generation cephalosporins, such as ceftriaxone or cefotaxime in *H. influenzae* is a growing cause of concern, since these antimicrobial agents are considered mainstays for severe *H. influenzae* infections. Resistance to third generation cephalosporins in *H. influenzae* occurs through the selection of mutations in key conserved residues of the *ftsI* gene, which codes for the essential penicillin-binding protein PBP3, which is the target of cefotaxime and ceftriaxone. The levels of resistance may vary, but high-level resistance to these agents is achieved after the stepwise acquisition of the mutations R517H or N526K in combination with L389F (Sanbongi et al., 2006). High-level cephalosporin resistance is still rare outside Japan and South Korea, although resistant strains are increasingly reported in countries from Asia, Europe and America (Deghmane et al., 2019).

Vaccination

As mentioned above, vaccination against *Haemophilus influenzae* type b helps prevent severe *H. influenzae* infections, reducing disease incidence and colonization by this pathogen. Several Hib conjugate vaccines have been developed and approved. All vaccines use polyribosylribitol phosphate (PRP) isolated from the Hib capsule. The immunogenicity of PRP is limited in children under 2 years of age so it needs to be conjugated with a protein carrier. Four different types of protein carrier have been used diphtheria toxoid (PRP-D), tetanus toxoid (PRP-T), CRM197 (a non-toxic variant of diphtheria toxin HbOC), and *Neisseria meningitidis* outer membrane protein complex serogroup B (PRP-OMP). The vaccine is administered in infancy in three doses at 2, 4, and 6 months of age, or in two doses at 2 and 4 months, depending on the formulation. In either case, a second dose is recommended between 12 and 15 months of age.

Bordetella

The genus *Bordetella* belongs to the *Alcaligenaceae* family and currently consists of 12 species: *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. brachialis*, *B. flabilis*, *B. sputigena*, *B. avium*, *B. hinzii*, *B. holmesii*, *B. trematum*, *B. petrii* and *B. ansorpii*. Of these, *B. pertussis*, *B. parapertussis*, *B. bronchiseptica* and *B. holmesii* are associated with respiratory infections in humans.

Microbiology

The genus *Bordetella* consists of gram-negative, non-sporulating coccobacilli of very small size (0.2–0.5–1 μ m). At the genomic level, *B. pertussis* and *B. parapertussis* show smaller genomes (4.0–4.8 Mbp) than many other species of the genus (more than 5 Mbp). Only the 50% of the genome of the species of the genus *Bordetella* is conserved in all species, and the signature of multiple genomic rearrangements, such as acquisition of insertion sequences, horizontal gene transfer, and acquisition of new genes and point mutations has likely driven the diversification and development of the different species of the genus (Park et al., 2012).

Bordetella are catalase positive and oxidize peptides but are not able to ferment carbohydrates. Some species are able to grow in simple synthetic media, however, the most clinically relevant species *B. pertussis* and *B. parapertussis* are very sensitive to toxic substances and metabolites present in multiple culture media. As a consequence, they need special media supplemented with blood and growth factors as niacin, in which they grow slowly at 35–37 °C. Other less pathogenic species can be easily isolated by routine microbiological procedures.

Bordetella also express a wide array of virulence factors that are usually controlled by complex expression systems that may act in response to different environmental conditions (BvgAS) (Gerlach et al., 2004). The most relevant virulence factors include adhesins, the filamentous hemagglutinin or the pertussis toxin (PT). The pertussis toxin is only expressed in *B. pertussis* by the *ptx* gene, since other species such as *B. parapertussis* or *B. bronchiseptica* the *ptx* gene is also present but lacks a functional promoter. The PT suppresses chemotaxis, oxidative responses and the activity of macrophages and neutrophils. On the other hand, the filamentous hemagglutinin and the fimbria type proteins FIM2 and FIM3 play important roles in adhesion and colonization of the ciliated epithelium of the upper respiratory tract (Mattoo and Cherry, 2005).

Epidemiology

B. pertussis and *B. parapertussis* are transmitted by droplets and cause human disease. *B. pertussis* is highly transmissible, since susceptible contacts transmission contact may be close to 90% and the infectious dose is around 100 colony-forming units (CFU). Once the bacteria are inhaled and introduced to the organism, they attach to the ciliated epithelial cells of the nasopharynx, leading to tissue lesion and the respiratory condition known as pertussis or whooping cough (Mattoo and Cherry, 2005).

Although the incidence and morbidity and mortality associated with *B. pertussis* infection has decreased since the introduction of the vaccine, pertussis is distributed throughout the world and causes outbreaks that can result in more than 15 million infections and 160,000 deaths per year, especially in less developed countries (Black et al., 2010; Yeung et al., 2017). The greatest morbidity and mortality associated with pertussis infection occur in young infants (<3 months of age) who often requiring hospitalization in an intensive care unit. In Europe, according to the European Centre for Disease Prevention and Control (ECDC), 33,133 cases of *B. pertussis* were confirmed during 2018. The highest notification rate was observed among infants below the age of 1 year (44.4 cases per 100,000 population), followed by 10–14-year-olds (22.0 cases per 100,000 population) (European Centre for Disease Prevention and Control, 2020). In developed and vaccinating countries, the cases of whooping cough are mostly restricted to neonates and unvaccinated young infants. A stage of permanent carrier is not observed with these pathogens, and the appearance of outbreaks in certain settings has been linked to insufficient vaccine coverage, changes in the circulating strains and decreased longevity of protection after vaccination (Watanabe et al., 2006).

B. bronchiseptica, *B. parapertussis*, and *B. holmesii*, can cause respiratory infections in humans but also in other mammals. *B. bronchiseptica* infects a wide range of hosts and occasionally causes cough illnesses in humans; in particular severe infections have been noted in persons who are immunocompromised such as patients with acquired immunodeficiency syndrome (AIDS).

Clinical manifestations

B. pertussis infection causes whooping cough, which has an incubation period of 7–10 days (maximum 21 days) (Cherry, 2005). The clinical presentation usually has three well-defined phases:

- 1st or catarrhal phase: After an initial incubation period of up to 10 days, the primary infection starts with symptoms that last 1–2 weeks and are indistinguishable from a common cold (including rhinorrhea, sneezing, malaise and fever). During this stage, the infection may be underdiagnosed due to lack of specificity of symptoms. This stage is the most contagious since in this period there is a peak in bacterial inoculum on the respiratory tract, posing a high risk to their close contacts which may lead to outbreaks.
- 2nd or paroxysmal phase: In this stage, the classic symptoms of pertussis appear, raising the suspicion of a diagnosis of *B. pertussis* infection. The patient has bursts of numerous rapid coughs, apparently due to difficulty expelling thick mucus from the tracheobronchial tree. At the end of the paroxysm, a long inspiratory effort is usually accompanied by a characteristic high-pitched whoop. It is common during the attack to become cyanotic. and children and young infants, especially, appear very ill and distressed (Hamborsky et al., 2015). Post-attack fatigue and vomiting episodes are common. The average number of daily episodes of paroxysmal cough is between 5 and 20, predominantly at night, triggered by stimuli such as laughter, crying or physical exercise. These episodes progressively decrease after the 3rd week. In adults, symptoms tend to be less severe than in children, but pertussis causes a long illness, with a mean duration of 6 weeks during which choking and vomiting are frequent.
- 3rd phase or convalescence phase: arrives after 2–4 weeks, where the number and severity of paroxysms decreases, but secondary complications may appear, such as secondary bacterial pneumonia, atelectasis, recurrent epistaxis, urinary incontinence, syncope, etc. (Kilgore et al., 2016).

Pertussis caused by *B. parapertussis* manifests with symptoms similar to those caused by *B. pertussis*, although it is generally less severe. Approximately 40% of cases are asymptomatic and if symptoms appear, they tend to be more moderate than those observed in infections caused by *B. pertussis* (Wirsing Von König et al., 2002). Other pathogens that may cause pertussis-like symptoms that should be considered for diagnosis include adenoviruses, respiratory syncytial virus, human parainfluenza viruses, influenza viruses, *Mycoplasma pneumoniae* and other agents (Paddock et al., 2008).

With regard to other infections caused by *Bordetella* spp., *B. holmesii* may cause respiratory symptoms and has also linked with different clinical conditions in immunocompromised hosts. *B. bronchiseptica*, *B. petrii*, *B. avium* and *B. hinzii* have been also exceptionally associated with respiratory symptoms and severe infections (e.g., bacteremia) in immunocompromised hosts with different underlying clinical disorders, including asplenia, HIV infections, or hematological malignancies (Toubiana et al., 2019).

Diagnosis

Several microbiological techniques are readily available, such as cultures, serology, and nucleic acid amplification tests for the diagnosis of *Bordetella* spp. infection. Although culture remains the gold standard since allows further typing and antimicrobial susceptibility testing, fastidious growth requirements make *Bordetella* spp. difficult to culture (only positive 12–60%) (Wendelboe and Van Rie, 2006). Different media are available for culture, such as RL medium, Bordet-Gengou, and Stainer-Scholte. Incubation should be performed for at least 1 week at 35–37 °C. Some media may include antimicrobials, such as cephalixin, to suppress concomitant growth of other bacteria.

Serology is applicable for the diagnosis of pertussis. Detection of a high level of anti-PT antibodies in the serum of an unvaccinated individual indicates infection. The use of serology in infants is not recommended because their immune system is immature and there is interference with maternal antibodies. The use of serology as a diagnosis is not recommended in those patients vaccinated for a period of 1 year, since it is not possible to differentiate the anti-PT antibodies from the vaccine or natural antibodies from the infection (Guillot et al., 2014).

Sensitive and specific NAATs are being increasingly implemented to overcome the limitations of culture and serology and can provide a quick result. Analysis of nasopharyngeal samples by PCR should be done between the first and third week after the onset of the cough. From the fourth week, false negative results can be obtained due to the decrease of bacterial DNA in the nasopharynx. NAATs targeting against the insertion sequence 481 (IS481) and insertion sequence 1001 (IS1001), are commonly used for the diagnosis of *B. pertussis* and *B. parapertussis*, respectively. However, both targets are present in other *Bordetella* strains, such as *B. holmesii* and *B. bronchiseptica* (Tizolova et al., 2013). For this reason, the CDC Pertussis and Diphtheria Laboratory has developed its own PCR to diagnose pertussis. The multi-target RT-PCR assay combines a pertussis toxin subunit 1 (ptxS1) singleplex assay and a multiplex assay targeting the multicopy gene IS481, *B. parapertussis* IS1001 (pIS1001), and *B. holmesii* IS1001-like (hIS1001) to distinguish between *Bordetella* species and identify co-infections (Lee et al., 2018) (Valero-Rello et al., 2019).

Molecular typing and discrimination of circulating strains may be important for outbreak management and surveillance. Despite *B. pertussis* show low genomic heterogeneity, some genomic targets show enough polymorphisms: the toxin gene (ptx), the toxin promoter (ptxP) and the pertactin gene (prn). A vast array of methods are available, including multilocus variable-number tandem repeat analysis (MLVA), pulsed-field gel electrophoresis (PFGE) and classic and next-generation sequencing (Williamson et al., 2012).

Treatment

B. pertussis and *B. parapertussis* are intrinsically susceptible in vitro to a wide range of antibiotics, including penicillins, macrolides, quinolones, tetracyclines and trimethoprim-sulfamethoxazole. However, they show resistance to most orally available cephalosporins.

The first line treatment for pertussis is macrolides. The accepted guideline for azithromycin is 500 mg 1st day, followed by 250 mg/day for 4 days, while for clarithromycin it is 500 mg/12 h for 7 days and for erythromycin 500 mg/8 h 7–14 days. If there is allergy or intolerance to macrolides, the alternative is trimethoprim-sulfamethoxazole (TMP 160 mg + SMX 80 mg) 12 h for 14 days. Antibiotic treatment does not modify the evolution of the infection if started after the third week of the disease, but it is considered indicated to reduce the risk of transmission. Symptomatic treatments (dexamethasone, salbutamol, etc.) have not shown superiority in the management of whooping cough (Pillay and Swingle, 2003).

Macrolide-resistant strains of *B. pertussis* are rare in most countries, although recently, an increasing number of strains carrying the A2047G mutation in the 23S rRNA, which is associated with macrolide resistance, have been reported in China and Vietnam (Kamachi et al., 2020).

There is no consensus on the best treatment for non-pertussis *Bordetella* infections. Because confirmatory diagnosis usually requires some time, patients with *B. holmesii* and *B. bronchiseptica* infections are usually treated for a *B. pertussis* respiratory infection. *B. holmesii* and *B. bronchiseptica* are generally poorly sensitive to macrolides and some cephalosporins, but low MICs have been reported for carbapenems and fluoroquinolones (Pittet et al., 2014; Kadlec and Schwarz, 2018). Further microbiological research is needed to determine breakpoints and the best antimicrobial treatment for these species.

Vaccination

Two acellular vaccines (dTdap for children and Tdap for adults) indicated for active immunization against diphtheria, tetanus and pertussis are currently approved by the FDA. Its composition includes detoxified pertussis toxin (PT), filamentous hemagglutinin (FHA) and Pertactina (PRN) (Sanofi Pasteur. DAPTACEL (Diphtheria and Tetanus Toxoids and Acellular Pertussis Vaccine Adsorbed) [package insert] U.S. Food and Drug Administration, n.d.).

Bartonella

The genus *Bartonella* encompasses fastidious and intracellular gram-negative bacteria belonging to the family Bartonellaceae. Currently this genus consists of more than 40 species that infect animals, with the majority of human diseases being caused by *B. bacilliformis*, *B. henselae* and *B. quintana*. The association of human diseases with other *Bartonella* species (*B. vinsonii*, *B. grahamii*, *B. washoensis*, etc.) is based on very limited information from case reports.

Microbiology

Bartonella are gram-negative, pleomorphic, intracellular, small (0.2–0.5 by 0.5–2 µm), intracellular bacilli. Because of the very low dividing time (approximately 24 h) of these bacteria on agar plates, conventional identification of this bacteria cannot be achieved through conventional biochemical tests and are therefore not useful for clinical diagnosis of infection. *Bartonella* species are oxidase and catalase and highly hemin-dependent, and can be isolated in agar cultures of enriched blood-containing media. The optimal growth temperature may vary between species, being from 25 to 30 °C for *B. bacilliformis* and from 35 to 37 °C for *B. quintana* and *B. henselae*. They can be cultured on solid media from blood samples, biopsies of eruptive lesions or subcutaneous nodules, requiring a prolonged incubation period (2–6 weeks).

Epidemiology

The main reservoir of *Bartonella* species are mammals (e.g., humans, rodents, cats and sheep, among others) and they are transmitted by vectors, mainly hematophagous arthropods and insects, such as fleas, sand flies, body lice and ticks. In addition, transmission may also occur through animal bites and scratches. At the geographical level, some species are circumscribed to specific regions in which the specific vector is distributed. Such is the case of *B. bacilliformis*, the etiologic agent of Carrion's disease, which only lives in areas between 1.000 and 3000 m altitude in the Andes Mountains of South America, as this is the endemic area of its vector, *Lutzomyia verrucarum* (Gomez and Ruiz, 2018).

Others, such as *B. quintana* and *B. henselae*, appear to have a worldwide distribution. Outbreaks due to *B. quintana* are mainly associated with homeless patients living under very poor conditions of hygiene and sanitation. This favors the infestation of the human body with the main vector of *B. quintana*, *Pediculus humanus*, and subsequent bacterial infection through inoculation of contaminated arthropod excreta through skin fissures. On the other hand, *B. henselae* main reservoir are cats, which are responsible of transmitting infection to humans through direct transmission of infective flea feces at the time of the scratch, causing the disease known as Cat Scratch disease. The disease tends to be more prevalent in regions with high prevalence of stray cats living outdoors and warm and humid climates that favor a major abundance of sand fleas (Boulouis et al., 2005).

Clinical manifestations

Bartonella species may infect humans and cause a plethora of different clinical manifestations. Here we summarize some of the most clinically relevant diseases caused by these species:

- Carrion's disease: caused by *B. bacilliformis*, it is characterized by a hemolytic bacteremia, consisting of a first acute phase (known as Oroya fever) of fever and severe anemia caused by *B. bacilliformis*-infected erythrocytes. The clinical course in this phase is severe and without treatment can be fatal (40–85% mortality) and is frequently observed in nonnative populations. After weeks of months after infection, the acute phase is followed by a chronic phase with the appearance of one or multiple skin lesions of vascular appearance, papular and pruritic, which bleed easily (known as Peruvian Wart, in Spanish "Verruga Peruana" (Kosek et al., 2000)). Myalgias, arthralgias, headaches and superinfections are also frequent, especially by *Salmonella* spp. These lesions may persist for months, but prognosis is favorable at this stage. The link between acute and chronic forms was documented in 1985 by Daniel Carrion, who died of Oroya Fever after inoculating himself with infected material from a verruga.
- Trench fever: 5-day fever or Wolhynia fever. It is caused by *B. quintana* and transmitted from person to person by the body louse, *P. humanus*. It was widely described in World War I, where the overcrowded conditions of the European armies in the trenches favored the spread of the disease. Nowadays we are assisting to the reappearance of this clinical disease, especially in disadvantaged social groups, which is called urban trench fever (Brouqui et al., 1999). The infection can range from asymptomatic to severe headache, high fever, asthenia and bone pain, especially in the pretibial area, and has an incubation period which ranges from 15 to 25 days. The fever is characterized by recurrence at 5-day intervals, hence the name of the entity. The disease may last several weeks without treatment during which bacteremia and the onset of endocarditis are common. *B. quintana* endocarditis is one of the most frequent cause of blood culture-negative endocarditis (Jackson and Spach, 1996).
- Cat scratch disease whose main agent is *B. henselae*. After scratching, an inflammation of the area that often resembles an insect bite occurs after 10–14 days, followed by enlargement of the lymph nodes draining at the site of contact (Lamps and Scott, 2004). The skin lesion usually disappears after some weeks. In 25% of cases, suppurative complications occur, although most infections are self-limited and resolve spontaneously. The large majority of cases the lymphadenopathy is accompanied with fever, chills, malaise and anorexia. Serious complications or dissemination to other organs rarely appear, and may include Parinaud's oculo-glandular syndrome, retinitis, osteolytic lesions, encephalopathy and thrombocytopenic purpura.
- Bacillary angiomatosis produced mainly by *B. quintana* and *B. henselae*, is a vascular proliferative disease that mainly affects immunocompromised patients (patients with immunosuppressive treatment, HIV with less than 100/mm CD4, etc.) and rarely immunocompetent patients. Skin lesions of unspecific size occur, which can be superficial and/or deep and may involve the subcutaneous tissues and bones. They are very vascular lesions, which bleed easily (similar to a Peruvian wart), and are accompanied by adenopathy in the area. When the vascular proliferations have hepatosplenic localization it is known as Peliosis. Hepatic and splenic peliosis may present with fever, abdominal pain, hepatosplenomegaly and increased acute phase reactants (Koehler et al., 1997).
- Subacute endocarditis. *B. quintana* and *B. henselae* account for most cases of this entity. The clinical presentation is characterized by nonspecific symptoms such as weight loss, fever and fatigue, accompanied by a mild and progressive infection of the endocardium. In patients who have not received antibiotic treatment, the most common etiologies of blood culture-negative endocarditis are *Coxiella burnetii* and *Bartonella* species, the former being responsible for 28–37% and the latter for 12–28% of cases (Chomel and Kasten, 2010).

Diagnosis

Most of specimens used for isolation or detection of *Bartonella* are blood or tissues with suspected infection. However, confirmation of the diagnosis of *Bartonella* infection is often a major challenge. Definitive diagnosis is made by isolation of *Bartonella* in

blood or tissue culture, which is usually difficult in most cases due to fastidious Bartonella growth. Often the diagnosis is made by complementary tests such as serology and molecular biology tests. Close communication with the Microbiology service is often key to getting to this point, since for Bartonella species the available clinical specimens and the patient underlying disease are particularly relevant for choosing the most optimal diagnostic approach. Indirect fluorescence assay (IFA) and enzyme-linked immunosorbent assay (ELISA), are available for the diagnosis of Bartonella infections and are of particular relevance for diagnosis of Bartonella endocarditis. Although they can be helpful for diagnosis, these techniques often result in lack of specificity and cross-reactivity between the different Bartonella species (Bergmans et al., 1997). As for molecular tools, an increasing number of laboratories allow the amplification of Bartonella DNA in various samples (valvular tissue, angiomas lesions, whole blood) by RT-PCR or the detection and sequencing of Bartonella 16S rRNA gene or other housekeeping genes that allow confirmation of the diagnostic suspicion and identify the pathogen at the species level (Fenollar and Raoult, 2004; Liesman et al., 2017).

Treatment

As we have seen, *B. bacilliformis*, *B. henselae* and *B. quintana* lead to different clinical manifestations, leading to a different therapeutic approach depending on the involvement they cause:

Treatment for Carrion's disease is differentiated for either the acute or chronic phase. In Oroya fever, the recommended treatment is ciprofloxacin 500 mg/12 h vo, 10 days or chloramphenicol 14 days. In the phase known as Peruvian wart, rifampicin 300 mg/12 h 14 days or streptomycin 15–20 mg/kg/day, 10 days. For cat scratch disease, no efficacy of antibiotic treatment (azithromycin) versus placebo has been demonstrated, except for a faster decrease in the size of the adenopathy in patients treated with azithromycin. When adenopathy is large, it can be drained by aspiration puncture. Treatment of trench fever and chronic bacteremia is successfully performed with the association of doxycycline 100 mg/12 h vo 6 weeks with gentamicin 3 mg/kg/day iv 2 weeks. In patients with bacillary angiomatosis and hepatic peliosis, the treatment of choice is erythromycin, and doxycycline can be used in those patients who do not tolerate erythromycin. Treatment may be prolonged to avoid the risk of recurrence, especially in immunocompromised patients. In cases of suspected Bartonella endocarditis, the consensus treatment according to The American Heart Association is ceftriaxone and gentamicin with or without doxycycline. When the diagnosis of Bartonella is confirmed, the consensus treatment is doxycycline 100 mg/12 h for 6 weeks and 3 mg/kg/day gentamicin for 2 weeks (Baddour et al., 2005). Valve replacement is often necessary due to embolic events and the formation of large valvular vegetations (Prutsky et al., 2013).

Mycobacterium

The family *Mycobacteriaceae* are a diverse group of bacteria that differ widely in several traits, such as their pathogenic potential in humans and animals, reservoirs, and growth dynamics in culture. The only genus of this family can be divided into four major groups based on fundamental differences in epidemiology, association with disease, and the ability to grow in vitro: those that belong to the *Mycobacterium tuberculosis* complex, *Mycobacterium leprae*, and *Mycobacterium ulcerans* and those referred to as nontuberculous mycobacteria (NMT).

Mycobacterium spp. contain mycolic acids in their cell wall and share this characteristic with bacteria of other genera such as *Gordonia*, *Nocardia*, *Rhodococcus* and *Tsukamurella*. This characteristic enables these bacteria to be differentiated from other bacteria based on staining techniques since the high mycolic acid content in the cell wall makes organisms resistant to discoloration with acid alcohol.

Mycobacterium spp. are aerobic, non spore forming, Gram positive, acid –fast bacilli (AFB). They are non motile, and most of them straight or slightly curved rods, with only a small number of species exhibiting some branching. Some species are pigmented, and this pigment may be constitutive (scotochromogenic), or induced only with exposure to light (photochromogenic) and finally others never produce pigment (nonphotochromogenic). Mycobacteria are different from most of other bacteria, these are slowly growing, require at least 5 days of incubation, and many of them one or more weeks for visible growth.

From 41 valid species in 1980, the genus *Mycobacterium* currently encompasses almost 200 recognized species and subspecies, many of which either can cause clinical disease, have been associated with disease, or have been isolated from clinical specimens without any known clinical correlation (Tortoli, 2014).

Mycobacterium tuberculosis

Tuberculosis continues to cause considerable morbidity and mortality globally. According to estimates of the World Health Organization (WHO), in 2018 there were approximately 10 million active cases, of which 3–4 million cases were infectious, with positive sputum smears. 8–7 million (87%) of these individuals reside in 30 high burden countries. Deaths due to tuberculosis occur in 1–3 million people worldwide each year (WHO, 2019). Thus tuberculosis is still a major cause of disease and death, and its elimination will be extremely difficult as long as, overpopulation, and multidrug-resistant (MDR) disease characterize large portions of the earth. Every year, more than half a million people become sick with rifampicin-resistant forms of tuberculosis, but in 2017, only 160,684 people were diagnosed or notified, and only 139,114 had started treatment (WHO, 2018). Currently, prevalence of rifampicin-resistant tuberculosis is increasing in several key countries including Russia, Myanmar, China and South Africa (Law et al., 2017).

Global tuberculosis incidence is estimated to be slowly declining by 1.6% per year, far from the 4–5% estimated to be required to reach WHO End TB Strategy targets (GBD Tuberculosis, 2015).

Although tuberculosis can affect any organ of the body, the lungs are virtually always the portal of entry. The bacilli are most commonly discharged into the atmosphere by aerosolization of pulmonary secretions by a diseased pulmonary patients in coughing, sneezing, speaking, and singing. Aerosol droplets dry rapidly, leaving tiny droplet nuclei, some of which contain a few bacilli (Wells, 1934). Droplets nuclei in the range of 1–10 µm can be inhaled, with the larger ones trapped in the upper nasal passages or expelled into the pharynx by the mucociliary mechanism of the lower respiratory tract and harmlessly swallowed and digested; smaller droplet nuclei may reach the alveoli and establish infection. Although, in theory, one droplet nucleus may be sufficient to establish infection, prolonged exposure and multiple aerosol inocula are usually required. Although homes are the focus of TB contact investigations, evidence is mounting that in high –TB settings, approximately 85% of transmission occurs in other social spaces including medical facilities, public transportation vehicles, workplaces, schools, churches, bars and other areas where people congregate. Other methods of transmission are rare. In the past, transmission of infection with *Mycobacterium bovis* through consumption of milk from infected cows was common, but these means have been brought under control in all developed countries by elimination of disease cattle and pasteurization of milk and milk products (Ayele et al., 2004).

The close contact of a smear-positive patient is at maximum risk of being infected, however, the disease is not as highly infectious as some of the viral infections. The ability of the bacilli to cause infection in newly exposed contacts depends on the adequacy of the innate antibacterial defenses of the person. Studies have shown that the infection rate among close contacts ranges from 25% to 50% even in the worst overcrowded and substandard conditions (Templeton et al., 1995; Ting et al., 1999). On the basis of epidemiological data, it appears that exposure generally must be close and sustained, the environment heavily laden with droplet nuclei, and the prospective host unprotected by inborn defenses, previously activated immune mechanisms, or both if an infection sufficient to produce disease is to be established.

In a recent study, immune responses found within individual granulomas suggest that local immune responses at the site of infection are as important in controlling tuberculosis infection as systemic immunity (Torrelles and Schesinger, 2017). Other studies show that some individuals exposed to tuberculosis do not become infected, whereas others rapidly succumb to infection and disease even, with minimal exposure (Seshadri et al., 2017).

In relation to the time course of progression from infection to disease, until now, the people newly infected with *M. tuberculosis* have the highest risk to progression to disease within the first several years after the infection. Analysis of historical data has

confirmed that incubation of *M. tuberculosis* is probably shorter than previously thought around 24 months (Behr et al., 2018). In general, 3–4% of infected individuals acquire active TB during the first year after tuberculin conversion and an additional 5% do so thereafter.

Various factors may influence the risk of developing tuberculosis in an individual or a population. The age and sex variables are also influenced by the timing of epidemic in the population, showing in developing world tuberculosis rates are higher among young adults, which indicates that primary transmission occurs in this age group. Children are at higher risk of contracting tuberculosis infection and disease. The majority of children of less than 2 years of age get infected from the household source case, whereas, with children older than 2 years of age, the majority of them become infected in the community.

Considerable evidence has documented the linkage of tuberculosis with HIV/AIDS (Glynn, 1998). Tuberculosis infection progresses to active disease in persons infected with HIV at a rate of 10% per year. HIV infected persons are highly susceptible to exposure to tuberculosis (CDC, 1993). HIV coinfection greatly increases the chances of reactivation of latent infection of tuberculosis and increases the rapid tuberculosis progression following primary infection or reinfection with tuberculosis (Miles Braun et al., 1991; Shafer et al., 1995).

Important work has also been done on socioeconomic risk factors that might be just as predictive of who becomes infected with, and sick from tuberculosis. In this manner, people from low socioeconomic status populations are known to be at high risk of becoming sick from tuberculosis (Oxlade and Murray, 2012). Although there are many factors involved, such as racial differences, crowding and availability of health care.

There are special populations from tuberculosis: prisoners have a higher chance of getting infected with tuberculosis mostly because of crowded living conditions and coinfection with HIV and injection drug abuse (Raina MacIntyre et al., 1997), patients in chronic mental hospital (Stead, 1981). Alcoholics have been found to have 10 times higher risk of developing tuberculosis than the general population in urban areas. This risk of active tuberculosis is substantially elevated in persons who consume more than 40 g of alcohol per day (Lonnroth et al., 2008). Cigarette smoking increases a relative risk of 1.5–2 for the development of tuberculosis (Bates et al., 2007). Individuals with immune mediated inflammatory disorders are also known to be at increased risk of developing active tuberculosis, particularly after the use of tumor necrosis factor (TNF). Now, screening for latent infection for *M. tuberculosis* has been recommended before TNF alpha inhibitor therapy is initiated, (Smith et al., 2011). Different studies have shown that malnutrition increases the risk of tuberculosis because of an impaired immune response. Tuberculosis disease can itself lead to malnourishment because of decreasing appetite and changes in metabolic processes (Cegielski and McMurray, 2004).

Other factors associated with an increased risk of developing tuberculosis are diabetes mellitus. A systematic review comparing 13 studies examining the association between diabetes and tuberculosis found that diabetic patients had about a threefold increased risk of developing tuberculosis when compared to those without diabetes (Jeon and Murray, 2008). Another review on treatment outcomes among patients with diabetes mellitus and tuberculosis found that the risk of death was 1.89 times higher compared to those without diabetes, with the risk increasing to five times higher for those with diabetes mellitus after adjustment for potential confounders (Baker et al., 2011). Healthcare workers are at increased risk of exposure to tuberculosis, a review by Sleider et al. showed that among healthcare workers in high income countries, the overall incidence of tuberculosis disease in the general population and native born healthcare workers was less than 10–25 per 100,000 per year (Seidler et al., 2005).

Clinical manifestations of tuberculous disease

Pulmonary and thoracic tuberculosis

Pulmonary TB has nonspecific clinical manifestations, and can even be detected in asymptomatic individuals in the course of contact studies or other examinations. It is usual for the patient to usually presents with symptoms of several weeks' duration, consisting of coughing, cough, expectoration, sometimes hemoptoic, chest pain and general symptoms (fever or fever, sweating, asthenia, anorexia, asthenia, anorexia and weight loss). Thoracic examination may be unremarkable or localized or asymmetrical sounds or rales may be auscultated or asymmetrical breath sounds may be heard. It is paramount to suspect the disease, and in any patient with respiratory symptoms and/or general symptoms of more than 2–3 weeks duration initiate diagnostic procedures, as well as in any patient with hemoptysis, irrespective of duration.

Pleural TB can occur in isolation or concomitantly with pulmonary TB. Chest radiograph shows the typical picture of pleural effusion which is usually unilateral and variable in size. Thoracentesis yields a yellowish pleural fluid, usually with the characteristics of a lymphocytic exudate, which should be used for the various diagnostic procedures.

TB may also involve the hilar and mediastinal nodes, and may or may not be associated with other forms of thoracic and/or cervical lymphadenitis.

Another thoracic structure that may be affected by TB is the pericardium, which manifests as a pericardial effusion or constrictive pericarditis, which may occur alone or in association with pleuritis or another form of thoracic TB. The clinical presentation is usually insidious. Ultimately, the symptomatology of pulmonary and thoracic TB is not specific to the disease, so a high index of suspicion is needed in patients with suggestive symptoms in order to make a diagnosis as early as possible and institute appropriate treatment (Perlman et al., 1997; Berh et al., 1999; Kline et al., 1995).

Extrathoracic tuberculosis

M. tuberculosis is preferentially found in well-oxygenated areas of the lung. However, by hematogenous route, it can implant itself in any other part of the body and multiply there to give rise to different forms of clinical manifestations depending on the site of

infection. Extrathoracic TB may be accompanied by systemic symptomatology, although this is less frequently observed. Patients with HIV or other immunodeficiencies, women and people of non-Caucasian race are more likely to manifest extra-thoracic forms of TB (Cagatay et al., 2004; Yang et al., 2004). Once the diagnosis of extrapulmonary TB has been made, the association with pulmonary TB must always be investigated, as they can coexist and, although the basis of treatment is the same, the diagnosis of pulmonary TB implies contagiousness, which requires contact studies to be carried out (CDC, 2005).

Tuberculosis of the central nervous system

Tuberculous meningitis is the most common form of TB in the central nervous system. With a fatal prognosis without treatment, treatment should be initiated as soon as there is a well-founded diagnostic suspicion. Onset symptoms are nonspecific (asthenia, anorexia, headache) and may last for several weeks. If left untreated, decreased level of consciousness and signs of neurological focalities appear. The British Medical Council (BMC) proposed a three-stage classification of the disease, from the absence of neurological involvement and consciousness to coma, which still retains its prognostic value today.

(NCCCC, 2006)

Osteoarticular tuberculosis

Mainly due to bacillary hematogenous dissemination, vertebral localization is the most frequent. The initial symptomatology is very unspecific, with a slow progression and a long delay in diagnosis. In advanced cases, the infection spreads to adjacent soft tissues, causes cold abscesses or abscesses to the back of the vertebra and can affect the spinal canal and cause spinal cord compression, sometimes requiring urgent surgery.

The most frequent locations are lumbar in older people and thoracic in younger people.

Urinary tuberculosis

Caused by hematogenous dissemination, the symptomatology is unspecific or even asymptomatic in early stages. The most frequent signs and symptoms are pollakiuria, dysuria and hematuria.

Genital tuberculosis

In men, the prostate and epididymis are the most frequent sites, and to a lesser extent the testicles and seminal vesicles. In women, the fallopian tube is the most frequent location and is responsible for 80% of genital TB. It is one of the most common causes of infertility in the world.

Lymph node tuberculosis

The most frequent localization is in the cervical and supraclavicular ganglia. Cervical tumor are the most frequent form of progression. Adenopathies tend to grow gradually and are initially rigid and painless in consistency. Adenopathies may undergo necrosis, show signs of inflammation with fistulization and drainage of caseum to the outside, known as scrofula (Cagatay et al., 2004).

Miliary tuberculosis

Due to hematogenous dissemination to multiple organs. Small nodules may be seen in the affected organs. Chest X-ray may show the typical millet-grain pattern with small pulmonary nodules, although it may be normal. Diagnostic suspicion is important in order to treat as early as possible.

Laryngeal tuberculosis

Currently occurs in less than 1% of patients with tuberculosis, the most frequent sign is dysphonia, which should raise suspicion of this condition, although it can occur with dysphagia, cough, hemoptysis. The differential diagnosis is with laryngeal neoplasia. Laryngeal tuberculosis is accompanied by bacillary pulmonary TB, and is therefore highly contagious.

Cutaneous tuberculosis

It is a manifestation of systemic disease, although it can be acquired by direct inoculation or by extension from a contiguous focus. It has different forms of presentation in immunosuppressed and immunocompetent patients such as verrucous tuberculosis or papulonecrotic tuberculous tuberculosis.

Gastrointestinal tuberculosis

Although the ileocecal location is the most frequent, can affect any part of the digestive tract. On endoscopy, it may present as a carcinoma or as warty or fistulized images.

Clinical manifestations in immunocompromised patients

The clinical presentation, radiology, severity and course of tuberculosis may be altered in the context of immunosuppression caused by some diseases such as solid neoplasms, hematological diseases, solid organ transplantation and HIV infection. The latter being the paradigm of the influence of immunosuppression on tuberculosis disease. In HIV-infected patients, exclusive pulmonary

involvement occurs in less than 50% of cases, with the remainder having exclusive or mixed extrapulmonary involvement. The signs and symptoms of tuberculosis in HIV-infected patients are often nonspecific and do not clearly distinguish the disease from other opportunistic infections.

The radiological presentation of pulmonary tuberculosis is highly variable, ranging from normal chest radiographs to extensive bilateral patterns. There are a large number of intrathoracic adenopathies. In extrarespiratory forms, peripheral lymph node involvement such as intrathoracic or intra-abdominal is very frequent. The development of explosive forms of tuberculosis has been reported at the beginning of antiretroviral treatment and anti-tuberculosis treatment. They do not have a worse prognosis or evolution and do not require specific treatment.

In patients with immunosuppression other than HIV, the typical presentation is extrapulmonary or disseminated. In solid organ transplant recipients, it has been associated with the use of anti-CD3 monoclonal antibodies or anti-TNF administration (Narita et al., 1998; DeSimone et al., 2000).

Mycobacterium leprae

M. leprae is an intracellular pathogen, cause of leprosy a chronic granulomatosis disease that affects the skin, peripheral nervous system, and mucous membranes. Patients with leprosy are classified as having paucibacillary or multibacillary disease. Paucibacillary (low numbers of organisms) disease is the milder form and is characterized by one or more skin macules. Multibacillary (large numbers of organisms) leprosy is associated with symmetric skin lesions, nodules, plaques, thickened dermis, and frequent involvement of the nasal mucosa. Person to person spread via inhalation of infectious droplet is the usual mode of transmission of *M. leprae* (WHO, 2020).

M. leprae incubation period can last up to 11 years. Several types of leprosy have been described, including indeterminate leprosy, tuberculoid leprosy, borderline tuberculoid leprosy, mid-borderline leprosy, borderline lepromatous leprosy and lepromatous leprosy. A few hypopigmented macules that can heal naturally, endure or advance to other types can be observed for intermediate leprosy. Tuberculoid leprosy is characterized by hypopigmented macules, with loss of thermic, tactile and pain sensations, and enlargement of nerves which can heal naturally, persist or advance to other types. In borderline tuberculoid leprosy, smaller but more lesions like tuberculoid leprosy and less nerve enlargement can persist, regress to tuberculoid leprosy or progress to other types. Mid-borderline leprosy is described by asymmetrically dispersed reddish plaques, with moderate loss of thermic, tactile and pain sensations, with swollen lymph nodes which can revert or progress to another type or persist. Numerous skin lesions including flat lesions, raised bumps, nodules and plaques and sometimes loss of thermic, tactile and pain sensations that can persist, revert to lepromatous leprosy or progress to other types are the characteristic features of borderline lepromatous leprosy. For lepromatous leprosy, initial lesions are observed as pale flat diffuse and symmetric regions that contains *M. leprae*, and initially hair loss is noted, and limb weakness, aseptic necrosis, lepromas, and disfigurement is observed as the disease progresses. Unlike other forms of leprosy, lepromatous leprosy does not regress to less serious types (Lockwood and Reid, 2001; Saonere, 2011).

In the past 20 years, 16 million cases of leprosy have been recorded according to the WHO. In 2013 to 2015 to the WHO, more than 200,000 new cases were reported each year, indicating that the disease is still progressing without hindrance. In 2017 and 2018 over 200,000 new cases were reported, whereby in 2018, 71% of cases was described in South East Asia, while the Americas and African region represented 15% and 10% of the new cases. The countries with most new cases were India, Indonesia and Brazil (WHO, 2020).

Mycobacterium ulcerans

Mycobacterium ulcerans is a strict pathogen of humans. Disease ranges from a localized nodule or ulcer to widespread ulcerative or nonulcerative disease, including osteomyelitis. If untreated, severe limb deformities with contractures and scarring are common. In Africa, the disease is referred to as Buruli ulcer, while in Australia, it is called Baringsdale ulcer. Nevertheless, disease mediated by *M. ulcerans* is the third most common mycobacterial disease in the world (Pfyffer, 2015; WHO, 2017a,b). In human, the unique pathogenic capacity of *M. ulcerans* is due to the secretion of a potent macrolide toxin, mycolactone, encoded by a plasmid that causes tissue damage and inhibits the immune response (Adusumilli et al., 2005). It is difficult to determine the true incidence of disease caused by *M. ulcerans* since it is not easily isolated in laboratories. Individuals of all ages and both sexes may be infected, many are children under 15 years of age (Marras et al., 2007).

Although *M. ulcerans* can lead to deep infections, such as osteomyelitis, the predominant clinical picture is cutaneous lesions. This may take the form of different clinical pictures depending on the stage of development of the disease. It initially appears as a painless papular or nodular lesion, which in women occurs on the upper extremities and in men on the lower extremities. Subsequently, due to subcutaneous necrosis, the epidermis becomes necrotic. Deep tissues may be affected. The lesions can evolve toward healing, giving rise to scars that can become disabling.

Nontuberculosis mycobacteria

Nontuberculous *Mycobacterium* spp. have been called a variety of names, from atypical mycobacteria to MOTT (mycobacteria other than TB), and today are most frequently called nontuberculous mycobacteria or NTM. For many years, the Runyon classification of *Mycobacterium* was utilized in clinical laboratories to provide a convenient way to differentiate among NTM based on the rate of growth of the organism from subculture and pigment production. With the increasing use of molecular and other nontraditional biochemical means of identification, this classification system is no longer universally used and has limitations. The increase of newly described species seen in the last few decades is in part the consequence of the availability and increased reliability of new DNA sequencing methods that can differentiate even closely related species and, in part, the consequence of an increased frequency of isolation of mycobacteria (Al Houqani et al., 2011; Adjemian et al., 2012). NTM can form biofilms on a wide range of organic (plastic, silicone, rubber and PVC) and inorganic (glass, metals, and metallic fluids of machines) materials due to their hydrophobic cell wall and their resistance to disinfectants, antibiotics or heavy metals.

According to the American Thoracic Society (AST)/Infectious Diseases Society of America (IDSA) 2007 statement, when NTM are suspected as the etiology of disease, definitive diagnosis should always be supported as the etiology of disease, definitive diagnosis should always be supported by repeated isolation of NTM from several specimens of the patient single specimen if is collected aseptically from a sterile body site (Griffith et al., 2007). Laboratory results should always be correlated with the individuals clinical presentation and radiological and histological findings to determine the clinical significance.

Mycobacterium avium complex

Pulmonary infection caused by The *Mycobacterium avium* complex (MAC) can occur in immunocompetent host; disseminated infections usually occur in people living with HIV. The most common presentations of MAC lung infections in immunocompetent individual are TB like apical fibrocavitary or interstitials nodular infiltrates and bronchiectasis. In children, cervical lymphadenitis is the most common presentation (Cassidy et al., 2009).

The MAC is acquired from the environment and is not thought to be spread from person to person. Recently, *M. chimera*, a species within the MAC, was implicated in causing disease from the use of contaminated heater-cooler devices used in open heart surgery (Haller et al., 2016; Perkins et al., 2016). Historically, the MAC included two species, *M. avium* and *M. intracellulare*. From *M. avium* specimens, four subspecies have been assigned; *M. avium* subsp. *avium*, *M. avium* subsp. *hominissuis*, *M. avium* subsp. *paratuberculosis* and *M. avium* subsp. *silvaticu* (Turenne et al., 2007).

M. avium subsp. *avium* is associated with avian TB, while *M. avium* subsp. *hominissuis* is the agent of disseminated disease in humans AIDS with low CD4 counts, chronic lung diseases in patients with cystic fibrosis (CF), or cervical lymphadenitis in children. *M. intracellulare* is primarily a respiratory pathogen in humans, and an association with disseminated diseases is less common.

Mycobacterium kansasii

M. kansasii it is the second most common cause of NTM disease in some regions of the United States and different countries of Europe. The isolation of the bacteria in human specimens is almost always associated with disease. The primary manifestation of *M. kansasii* infection resembles that of pulmonary TB, with cavitary infiltrates in the upper lobes, but noncavitary and nodular bronchiectatic lung disease has also been observed. Risk factors include pneumoconiosis, chronic obstructive lung disease, malignancy, and alcoholism (Griffith et al., 2007; Falkingham III, 2015).

Mycobacterium mageritense. It was first isolated from a patient in Malmo, Sweden and it is usually recovered from sputum or cervical lymph nodes of children or adults with underlying chronic pulmonary disease (Griffith et al., 2007).

Mycobacterium xenopi

The clinical and radiological disease manifestations of this bacteria vary according to the patients immunological status, and can be classified into three groups: a cavitary form in patients with pre-existing pulmonary disease, a solitary nodular form in immunocompetent patients, and an acute infiltrate form in immunosuppressed patients. Extrapulmonary cases with joint and soft tissue infections have also been observed (Okano et al., 2016).

Mycobacterium haemophilum

This mycobacteria have special growth conditions (optimal growth temperature of 28°–30° and medium solid with hemin or hemoglobin) is often underrecognized. Most infections are reported in AIDS patients or with solid organ transplants, bone marrow recipients, or long term steroid user. The classical clinical presentation is multiple skin lesions or ulcerations appearing on the extremities that are occasionally associated with abscesses, fistulas, or osteomyelitis. In children caused cervical lymphadenitis.

Mycobacterium marinum

M. marinum is the cause agent of swimming pool or fish tank granuloma, which is the result of finger, hand, arm, elbow, knee or toe soft tissue injuring freshwater or saltwater due to punctures from fins of fish or shrimp or from cleaning of fish tanks or swimming pools. The typical presentation is a single papule on an extremity that may progress to a shallow ulcer, usually 2–3 weeks after inoculation. Severe complications may also include osteomyelitis of the bones and tenosynovitis and arthritis of the joints (Griffith et al., 2007).

Mycobacterium szulgai

Recovery of *M. szulgai* from the environment is rare and very unusual. Isolation of the bacteria in clinical laboratories almost always has clinical significance. The clinical presentation of pulmonary infections with *M. szulgai* is indistinguishable from that of TB and usually develops in middle aged men with alcohol abuse, smoking, obstructive pulmonary disease. Other extrapulmonary clinical manifestations may include cervical lymphadenitis, cutaneous infections, osteomyelitis, tenosynovitis, bursitis or disseminated infections in both AIDS patients and immunocompetent patients (Griffith et al., 2007).

Mycobacterium scrofulaceum. Its name is derived from the histological term scrofula, used to describe infections of the cervical lymph nodes by mycobacteria. It is a common cause of mycobacterial cervical lymphadenitis in children (Wolinsky, 1995).

***Mycobacterium abscessus* complex**

These organisms often cause infections of skin and soft tissue, severe lung infections can occur in persons with underlying chronic lung disease, including patients with CF, and disseminated disease. Although the taxonomy of organisms belonging to the *Mycobacterium abscessus* complex has been somewhat controversial, whole genome sequencing data strongly support the presence of three subspecies: *M. abscessus* subsp. *abscessus*, *M. abscessus* subsp. *bolletii*, and *M. abscessus* subsp. *massiliense* (Tortoli et al., 2016).

M. abscessus is a frequently isolated respiratory NMT, after the MAC, and accounts for more than 80% of all rapidly growing mycobacterial respiratory infections. Patients with lung disease due to *M. abscessus* are usually white, female nonsmokers older than 60 years of age without predisposing factors. Predisposing conditions that are commonly associated with *M. abscessus* pulmonary infections are bronchiectasis with reticulonodular lung infiltration, CF and rarely lipoid pneumonia and gastrointestinal disorders.

***Mycobacterium chelonae* complex**

It is a pathogen a key human opportunistic pathogen, rapidly growing mycobacterium that is widely recoverable from human made environments as tap water or from fresh water and seawater. The most common clinical manifestations are skin, soft tissue and bone infections. Disseminated diseases have been described in immunocompromised individuals, especially in those receiving high dose steroids. Infection may also be associated with ophthalmic surgery or contact lens wear (keratitis). Pulmonary infections by *M. chelonae* are less common than are those by *M. abscessus* (Umrao et al., 2016).

***Mycobacterium fortuitum* complex**

Includes the species *M. fortuitum*, *M. peregrinum*, *M. senegalense*, *M. setense*, *M. septicum*, *M. porcinum*, *M. houstonense*, *M. boenickei*, *M. brisbanense* and *M. neworleansense*.

Frequently is associated with skin, soft tissue, and bone infections, while it rarely causes pulmonary diseases, except in cases of lipoid pneumonia, gastrointestinal disorders, or disseminated diseases. Skin and soft tissue infections are common after mastectomy and similar plastic surgery interventions or cardiac surgery.

Microbiological diagnosis

Although multiple advances have been made in the diagnosis of tuberculosis, no reliable, simple, point of care exists to definitively diagnose the disease. Clinicians often seek bacteriological diagnosis, but this evidence is also supplemented by clinical findings, radiological evidence.

The samples should be representative of location and symptoms. The most common location in TB and NTM infections is the lung. In expectorating patients 2–3 series samples of early morning sputum is sufficient. When there is no expectoration, samples may be obtained with a bronchoscopy, through bronchial suction or bronchoalveolar lavage. In children or in situations without access to bronchoscopy, gastric suction may be used as an alternative. With kidney disease series samples of early morning urine is used. In cases of tissue or organ compromise, the samples are obtained by puncture or preferably biopsy. If there is suspicion of disseminated infection, blood, bone marrow may be useful. Biological fluids, such as cerebral spinal fluid, articular pleural fluid or others fluid will be indicated in their clinical presentations, when it is not possible to obtain a relevant biopsy.

Achieving optimum sensitivity should take into consideration: obtainment of sterile recipients, appropriate minimum volume, transport, quality of the samples, repetition of multiples test in the samples reduces.

Microscopy

Direct smear microscopic examination with Ziehl-Neelsen (ZN) staining is commonly used to detect AFB, especially in low-income countries, owing to its rapidity, low cost and predictive value for detecting pulmonary TB. The ZN staining, which colors the mycobacteria red and the remaining structures blue. Furthermore, fluorescence microscopy (FM) using auramine O/auramine rhodamine staining has approximately 10% greater sensitivity than ZN with similar high specificity and rapid diagnosis. The FM method has been further improved by a more advances, cost effective and stronger light source using light-emitting diodes (LEDs). The florescent colored mycobacteria on a dark background. As with all laboratory procedures, strict quality control is needed for acid fast staining or rates of false positives and negative quickly rise.

Microscopy is the primary method of examination for people with TB symptoms, but it has limitations such as laborious and times-consuming procedures for the technician. The specificity of the stain is high, with few distinguishable exceptions from its morphology (*Nocardia*, *Rhodococcus*, *Tsukamurella*, *Cryptosporidium*, *Cyclospora* and *Isospora*) since the majority of the microorganisms do not stain red o fluorescent.

Because acid –fast artifacts may be present in the AFB smear, morphology must be examined for the presence of long and typically acid-fast rods or coccobacilli that may appear slightly curved, beaded, isolated, in pairs or in groups and stand out clearly the background. Using auramine O stain, acid –fast organisms stain yellow-green (if auramine and rhodamine are used, AFB will fluoresce orange-yellow. Depending on the mycobacterial species, different morphologies may be observed on stained AFB smears. When stained from liquid medium *M. tuberculosis* often demonstrates cording. Some NTM species can exhibit cording as well, albeit rarely, such as the *M. avium* complex, *M. kansasii*, *M. goodii*, *M. chelonae* and *M. marinum*.

Currently recommended that all positive AFB smears be confirmed either by a second reader, by retaining the slide (if a fluorescent stain was used) using a Ziehl-Neelsen stain, or by initially preparing two AFB smears, one for the fluorescent stain and other for the Ziehl-Neelsen stain.

The sensitivity is conditions by factors such as the extent of the disease, the prevalence, the sample volume, concentration of mycobacteria and above all, the sample type and number of organisms in the specimen, laboratory processing. The limit of sensitivity would be between 50,000 and 100,000 mycobacteria/ml overall sensitivity may range between 20% and 80% of processed samples, depending on their anatomical type and origin. In respiratory samples it is higher, particularly in carious lesions, and in tissues, such as enlarged lymph nodes (50–80%). Sensitivity is very poor in biological fluids due to the low concentration of mycobacteria.

The stain from the concentrate after decontamination of the sample for the culture is 11–26% more sensitive than that directly made from the sample. Stains may be closely observed, at least 300 fields in optic microscope and 30 for florescent staining, prior to issuing a negativity report.

The optimum number of sputum specimens to establish a diagnosis has been examined in several studies that have served to support recommendations to decrease the minimum number of sputum specimens examined from 3 to 2, assuming that they are examined in a quality–assured laboratory. In a systematic review of 37 studies on the yield of sputum AFB smear microscopy, it was found that, on average, the initial specimen was positive in 85% of the all patients ultimately found to have AFB detected. The second specimen was positive in an additional 11, 9% of patients, and the third specimen was positive in a further 2.3% of patients.

Culture methods

The culture is the most sensitive diagnostic method. For the isolation of mycobacteria, the use of a liquid medium in combination with at least one solid medium is essential for good laboratory practice (Esther et al., 2011) It has been estimated that detection limit between 10 and 100 bacteria/ml. Its main drawback is the long incubation period, from several days up to 6 weeks before a final negativity report may be issued. Samples where flora or other bacteria are present, such as those of respiratory origin, they should be previously eliminated through a chemical decontamination process with the preservation of mycobacteria. The methods most well known is based on the use of NaOH and N-acetyl-L-cysteine (Kubica method). Of significance, some decontamination/concentration procedures are know to be compatible with egg-based media only and may not be used with any other media not containing egg yolk. These procedures include the use of Zephirantrisodium phosphate (Z-TSP), sodium lauryl sulfate, cetylpyridinium chloride or other quaternary ammonium compounds. The proportion of cultures will be contaminated despite decontamination, between 3% and 5% is considered acceptable, although it depends on the type of samples of each laboratory. Samples which contain *Pseudomonas aeruginosa*, capsulated bacteria, fungi and yeast, among others, will be more likely to contaminate the cultures. At present, for primary isolation from clinical samples the combined use of a liquid culture and solid culture is recommended. The most well known of both types are Lowenstein–Jensen and Middlebrook 7H11. The majority of liquid media used in diagnosis are semi-automated, based on the use of incubators which are capable of detecting growth by O₂ consumption or production of CO₂. They usually use Middlebrook 7H9 as the base medium, with enriched supplements and antibiotic solutions to neutralize microorganisms which have resisted decontamination, Three methods are the most common: VersaTREK (Thermo Fischer Scientific, Oakwood Village, OH, US), BactT ALERT 3 D (BioMerieux, Marcy L' Etoile, France) and MGIT960 (Becton Dickinson, Sparks; MD, US).

The cultures for the majority of mycobacteria are incubated a 35–37 °C. The species which cause skin and soft tissue diseases, such as *Mycobacterium ulcerans*, *Mycobacterium marinum*, *Mycobacterium haemophilum* and *Mycobacterium chelonae*, grow better at 25 °C and 30 °C. In contrast, *Mycobacterium xenopi* grows better a 42 °C and *Mycobacterium thermoresistibile* at 52°. Others species need specific supplements to grow in cultures, *M. haemophilum* which requires hemin, hemoglobin of ferric ammonium citrate solution

or *Mycobacterium genavense*. Tubes media should be incubated in slanted position with screw caps loose for at least 1 week to ensure an even distribution of the inoculum. Plated medium, ideally placed into CO₂ permeable plastic bags or sealed with CO₂--permeable tape, should be incubated with the medium side down if all the inoculum has not been absorbed.

The cultures are monitored continuously in liquid culture equipment, detecting potential positivity when they are produced. The solid cultures are inspected 1–2 times/week for the first 3 weeks and once during the following 3 weeks. All solid media should be examined within 3–5 days after inoculation to determine if there is contamination. The performance in culture is observed with the use of automated liquid cultures. With regard to the detection period of positive results, the majority become positive between the first and third week. The mean is 14 days. For samples with positive bacilloscopy, the positivity drops to 13 days for *M. tuberculosis complex* isolation. When the bacilloscopy is negative, this takes place between 17 and 16 days for MTC and NTM respectively. The solid cultures are positivized between the second and fourth week. Overall, almost 100% of solid and liquid cultures are positivized during the first 4 weeks. Recovery in liquid media is considerably superior to that of solids, especially for isolation of NTM. Specimens with positive AFB smears that are culture negative should be held an additional 4 weeks. Culture negative specimens that are positive for mycobacteria by one of NAATs or for cases with a high suspicion of tuberculosis should also be held an additional 4 weeks.

Nucleic acid amplification test

Algorithms for testing specimens from patients suspected of having tuberculosis should include a nucleic acid amplification test (NAAT). Guidelines from the CDC recommend the performance of a TB NAAT on at least one respiratory specimen from patients with signs and symptoms consistent with pulmonary tuberculosis. This is especially important if diagnosis of tuberculosis has not yet been made and the test result would alter patient care and/or TB control activities and can predict drug resistance (CDC, 2009). The NAAT should ideally be performed on all first time patients with suspected TB, and results should be reported within 48 h of specimen receipt.

It is important to consider that the sensitivity of amplification techniques is lower than that of the culture in those samples with negative stain, and therefore they cannot be used to rule out disease. Although the specificity of NAATs for tuberculosis diagnosis is very high, the sensitivities vary widely and depend on both the AFB smear status of the specimen (positive or negative) and the specimen type (Cepheid, 2015). Disadvantages of the molecular detection of the *M. tuberculosis complex* directly from clinical specimen include the inability to differentiate among species within the *M. tuberculosis complex*. In addition, a positive NAAT results does not differentiate between live and dead organisms. For this reason, amplification technologies should not used on specimens collected from patients who have received antituberculosis drugs for more than 7 days or have received such therapy in the last 12 months prior to collection. Furthermore, approximately 4% of pulmonary and 19% of extra pulmonary specimens have substances that are inhibitory to amplification (determined by a failed internal amplification control). Since it is rare that all specimens from a given patient show inhibition, testing of multiple samples can be advantageous (Hologic, 2013; Cheng et al., 2005).

To increase the sensitivity of these test and achieve similar results to the culture, the inhibitors found in the sample must be efficaciously eliminated to detect ≤ 10 –100 mycobacteria/ml, the lower limit of culture detection.

In 2010, the Xpert MTB/RIF (Cepheid, Sunnyvale, CA, US) appeared as a totally automated method, with minimum handling prior to the introduction of the sample in the cartridge where the whole reaction was to take place. It is authorized for use with AFB smear –positive and AFB smear negative expectorated and induced raw sputum specimens as well as processed sputum sediment (Cepheid, 2015). The Xpert MTB/RIF technique consist in a nested PCR at real time of the *rpoB* gene, which codes for sub-unit of the polymerase RNA. It uses 5 genetic probes of molecular beacon type, each one marked with a different fluorophore. It totally covers the area of 81 base pairs, between codons 426 and 452 of the *rpoB* gene determinant of rifampicin resistance. In this way it simultaneously reports the presence of MTC and the most frequent mutations in the *rpoB* gene, predicting resistance to rifampicin which in the majority of cases is connected to multiresistance. The low sensitivity of this system in paucibacillary samples has driven the same company to develop an Xpert MTB/RIF Ultra system which collects a larger sample volume than the previous model and adds 2 new targets which are found in a greater number in the MTC (IS6110 y IS1081) genome. Both changes have successfully increased sensitivity, which has led the WHO to propose its use, particularly in cases of patients infected by HIV and pediatric patients (WHO, 2017a, b). Other methods available on the market in our environment for the direct detection are those produced by Hain Lifescience Fluorotype MTB (Brucker) is a semi automated method which has recently been marketed, based on real time PCR. Initial assessment indicates a specificity of 98.9% with sensitivity of 100% for samples with microscope positivity and 56,3% for microscope negativity (Hofmann-Thiel et al., 2010). In order to increase sensitivity in diagnosis recent literature reports different proposals which may possibly be introduced in the future. It combines several DNA targets with several lavages to reduce the presence of the qPCR inhibitors with posterior amplification of 2 specific MTC targets, IS6110 and *sen X3-regX3* (XtractTB system) (Reed et al., 2017), to raise test sensitivity and specificity and minimize the probability of false negatives.

Lastly although trends lie in the use of commercial automated or semi-automated test, the WHO has recommended the use of loop mediated isothermal amplification or LAMP technique in its rapid diagnostic strategy of TB (WHO, 2016). Amplifies target DNA with high specificity, efficiency and rapidity under isothermal conditions requiring only a heat block and allows to detect visually DNA directly from clinical sputum samples without purification process of DNA, in less than 2 h and minimal equipment.

Detection of mycobacterial antigens in urine

Detection of *M. tuberculosis* antigens in urine may have some usefulness in diagnosing TB in patients with advanced AIDS, particularly in countries where coinfection is highly prevalent. Urine based antigen testing is attractive at the point of care (POC) level because urine is easy to collect and store, and lacks the infection-control risks associated with sputum collection. Especially, urinary detection of mycobacterial lipoarabinomannan (LAM) as a target antigen has emerged as potential POC test for active TB and/or HIV patients. LAM antigen is a lipopolysaccharide present in glycolipids of mycobacterial cell walls, which is released from metabolically active or degenerating bacterial cells and appears to be present only in people with active TB disease and/or with severe immunosuppression in their urine (McNerney and Daley, 2011; Chatterjee et al., 1991). A simple low cost lateral flow version, urine lateral flow LAM (LF-LAM) assay has been developed, and this lateral flow device is easy to perform rapidly within 30 min at the POC test diagnosis of TB and/or VIH using the Determine TB-LAM (Alere, Waltham, MA, USA). LF-LAM has been evaluated and reviewed in several studies for the detection of active TB infected with HIV, who are severely immunocompromised, and WHO is not recommended for diagnosis of TB (pulmonary or extrapulmonary) the use of LF-LAM, with the exception of people living with HIV, who has low CD4 counts or who is seriously ill in 2015 (WHO, 2015).

Genetic methods applied to the direct samples in diagnosis of nontuberculosis mycobacteria (NTM)

Molecular diagnosis of the NTM directly in the clinical sample has been the focus of less attention than the diagnosis of TB, probably due to incidence and epidemiological consideration. Anyplex Plus MTB/NTM combines the identification of MTC and of *Mycobacterium* sp. in a single amplification in real time. Another would be the Genotype NTM DR (Hain Lifescience Bruker) test which is able to detect mutations of resistance to macrolides and aminoglycosides while simultaneously identifying several species of NTM frequently isolated in clinical samples such as *M. chelonae*, *M. avium*, *M. intracellulare*, *M. chimera* and 3 sub-species of *M. abscessus* (sub. abscessus, sub bolletii and sub massiliense). No contrasted experience exists as of yet with regard to its use directly on clinical samples.

Immunological diagnosis

Individuals infected with *M. tuberculosis* with no clinical evidence of disease have latent tuberculosis infection (LTBI). They have been infected with *M. tuberculosis* but do not have TB disease. To test LTBI, a skin or blood test is performed to detect a cellular immune response to tuberculosis antigens, indicating prior infection.

The tuberculin skin test (TST) has been performed by injecting a small amount of TB-purified protein derivative (PPD) into the skin in the lower part of the arm. A person given the TST must return within 48–72 h to have a trained health care worker look for a reaction on the arm. If the skin area reacted to the antigen and is larger than or equal to 10 mm, it is considered a positive reaction (Froeschle et al., 2002). However, the TST gives false-positive results in people who have been vaccinated with *Bacillus Calmette–Guérin* (BCG), a vaccine for TB, non tuberculous mycobacterial infection, and false-negative responses in immunocompromised individuals. False negative reaction occur in at least 20% of all persons with known active TB. Protein malnutrition diminishes all cutaneous delayed hypersensitivity reactions. Sarcoidosis may cause false negative TST results. Vaccination with live virus vaccines (measles, smallpox), corticosteroid therapy may cause false negative.

Although tuberculin cannot sensitize an uninfected person, it can restimulate remote hypersensitivity that has deteriorated. This booster effect (a positive tuberculin test result after a negative one) develops within several days after a first injection and may be persistent. This problem is circumvented by retesting nonreactive 1–3 weeks after the initial test. If the second test result is positive, this indicates boosting rather than recent tuberculin conversion.

Others test, with interferon gamma release assay (IGRA) measures host cellular immune response to *M. tuberculosis* antigens in whole –blood samples.

The presently available blood IGRA is QuantiFERON-TB Gold In-Tube test (QFT-GIT, Cellestis, Australia) and T-SPOT.TB test (T-Spot, Oxford Immunotec, UK) which are the US FDA approved as indirect and adjunct tests for the TB infection (WHO, 2011). For the QFT-GIT test, fresh blood containing viable white blood cells is incubated with controls and single mixture of synthetic peptides representing ESAT-6, CFP-10, and TB7.7. Concentration of IFN- γ released in the plasma separated from blood is determined by enzyme-linked immunosorbent assay (ELISA). The next generation QuantiFERON-TB Gold Plus (QFTPlus) test has been FDA approved and is stranding to be rolled out in the United States and Europe. QFTPlus contains a fourth tube with short peptides from CFP-10, which are designed to elicit increased CD8⁺ T cell production of interferon- γ . There are only a few studies comparing the QFT-GIT and QFTPlus, and these suggest comparable results or perhaps slightly improved sensitivity of the QFTPlus in elderly or immunocompromised populations. For T-Spot test, peripheral blood mononuclear cells (PBMCs) are incubated with controls and two mixtures of peptides representing ESAT-6 and CFP-10, and the number of IFN- γ producing cells (spots) in the response to antigens is measured (Mazurek et al., 2010).

These test overcome several limitations of the TST including false positive results from environmental mycobacterial exposure or BCG vaccination, operator-dependent variability in test placement and regarding, and the need for a follow-up visit to examine skin induration.

Data on the performance of the interferon- γ release assays in children are limited, and guidelines differ on the optimal test. The ATS/IDSA/CDC guidelines recommend use of the same criteria as in adults for children aged 5 years and older. For children younger than 5 years, these guidelines recommend the TST, recognizing the limited data.

Antimicrobial susceptibility testing for the *Mycobacterium tuberculosis* complex

Antimicrobial susceptibility testing (AST) should be performed on at least the initial isolate from each patient with TB. The AST can be repeated after 3 months or earlier, if a patient remains culture positive and/or is not responding to treatment (Lewinsohn et al., 2017). Once a culture has been confirmed as *M. tuberculosis* complex, AST should be performed by a growth based method. This method should include at a minimum, AST for the first-line antituberculous drug rifampin and isoniazid (2 concentrations), ethambutol and pyrazinamide. If Rifampicin resistance or resistance to any two these drugs is detected, testing for susceptibility to additional second line drugs should be performed.

There are others genotypic testing, which correlates specific mutations in the isolates genome with known drug susceptibility patterns.

The agar proportion (AP) method is most commonly used to determine phenotypic drug resistance. The AP compares growth on the of appropriately diluted inocula on drug containing media versus growth on the drug-free media and is reported as proportion resistant. For most drugs, resistance is significant when growth on drug containing media exceeds 1% control; 6–10% resistance or more indicates that the drug will and nothing to multidrug therapy. Liquids broth systems, such as BACTEC, in MGIT tubes containing the critical concentrations of drugs can be inoculates from solid or liquid *M. tuberculosis* isolates. A categorical susceptibility or resistant result is provided. The VersaTREK method is an automated system used for growth and detection of mycobacteria as well as AST. Both methods are FDA cleared for rifampicin, isoniazid, ethambutol, pyrazinamide.

The TREK Sensititre method (ThermoFischer Scientific, Oakwood Hills, OH) is a semiautomated research use only broth microdilution method for susceptibility testing of mycobacteria in a microtiter plate format. A total of 12 drugs are provided, each with a minimum of 7 dilutions on the standard plate. This test determines MIC values, but there are no guidelines for the interpretation of susceptibility or resistance results.

Molecular methods detect mutations in genes associated with resistance to anti-TB drugs. These methods are rapid and specific, but phenotypic AST must still be performed, as genotypic resistance may not always translate to phenotypic resistance.

Most commonly used are test for rimpacin resistance, which predicts poor treatment outcomes and is a surrogate marker for multidrugs TB. Assays detect mutations in the 81 base pair *rpoB* gene, which encodes the β subunit of RNA polymerase and correlates with greater than 96% of RIF resistance. Resistance to isoniazid is more complex and is encoded by multiple genes, including the catalase peroxidase gene *kat G*, the gene *ihnA* gene involved in fatty acid biosynthesis. The X pert assay is an FDA cleared, rapid, real-time PCR test that simultaneously detects the presence of the *M tuberculosis* complex and the mutations in the RRDR of *rpoB*. The Genotype MTBR plus Version 2 assay is a PCR based line probe assay for the detection of *M. tuberculosis* complex, mutations in the *rpoB* gene associated with resistance to rifampicin, and mutations in the *lhnA* and *KatG* genes associated with resistance to isoniazid. These fast test can be performed directly on the specimen or from culture isolates. Genotype MTBDRsl assay, which detects resistance to fluoroquinolones and second line injectable drugs in culture isolates and smear positive sputum samples and thereby can be used to identify XDR TB. Sequencing methods can be used to target a variety of genes to determine mutations associated with resistance. These sequencing methods are laboratory developed test but can still play an important role in AST for the *M. tuberculosis* complex.

Antimicrobial susceptibility testing for nontuberculous mycobacteria

The role and relevance of in vitro AST of nontuberculous micobacteria to guide the treatment and clinical management of patients with NMT disease are under continuous debate. The base of this debate is that the clinical response to antimycobacterial drugs or antibiotics has been shown to correlate with only some compounds and in only some NMT. On the other hand, most clinically significant NTM isolates already show intrinsic resistance or high in vitro breakpoints for several antibiotics upon first isolation (Brown-Elliott et al., 2012).

The gold standard method for AST of rapidly and slowly growing NTM is broth microdilution assay, a commercial research use only product is the TREK Sensititre plate. AST of rapidly growing NTM should have rigorous quality control using CLSI recommended reference strains to ensure not only quality testing but also reproducibility of MICs within the recommended and acceptable ranges from antimicrobials tested. Isolates that are susceptible to clarithromycin should be further incubated for 14 days to rule out inducible macrolide resistance. MIC results for imipenem, meropenem and tetracycline may be invalid after more than 5 days of incubation because of stability related problems with these drugs (Brown-Elliott et al., 2012. Genotype NTM-DR ver 1.0 (Bruker) detect resistance macrolide and aminoglycosides *rrl* gen, *erm* gen and *rrl* gen. (Brown-Elliott et al., 2015).

For slowly growing NTM recommendations of the CLSI include clarithromycin susceptibility testing for new and previously untreated MAC isolates. There is no recognized value for testing of MAC isolates against first line antituberculosis drugs. Previously untreated *M. kansasii* isolates should be tested against rifampin only. If resistance to rifampin is detected, should be tested against a panel of secondary agents, including ethambutol, isoniazid, clarithromycin, fluoroquinolone, amikacin, sulfonamides and linezolid.

M. marinum isolates do not require susceptibility testing unless the patients fails treatment after several months. There are no current recommendations for one specific method of in vitro AST for fastidious NTM species (*M. haemophilum*) and some less commonly isolated NTM.

Treatment of tuberculosis

Treatment regimens that meet all the favorable requirements and have been universally recommended are 6 months with rifampicin, isoniazid, ethambutol and pyrazinamide for the first 2 months, followed by 4 months with rifampicin and isoniazid.

When the isolate is identified as sensitive to these drugs, ethambutol can be withdrawn. Exceptionally in paucibacillary cases, three drugs could be used in the initial phase.

Children generally have a good tolerance to pharmaceuticals. Treatment is the same as for adults, but the dose is adjusted to weight. The regimen should not be changed during pregnancy or breast-feeding.

Treatments in special situations

1. Patients with chronic liver disease

Treatment should be attempted with a standard regimen, with close monitoring of liver function. In cases of advanced liver disease, one of the three most hepatotoxic drugs, preferably pyrazinamide, should be withdrawn.

In the case of acute hepatitis or terminal stages of chronic liver disease, treatment without potentially toxic drugs should be chosen. These include a quinolone, an injectable and ethambutol or cycloserine.

2. Chronic renal failure

No modification of standard treatment is necessary. Only in patients with a creatinine clearance of less than 30 ml/min or in patients on hemodialysis programs it is recommended to administer the treatment 3 times a week, maintaining the same dose as the daily regimen.

3. Extrapulmonary forms of tuberculosis

It is usually recommended to use the same treatment regimens as for pulmonary tuberculosis and to prolong the duration of treatment in some special situations, e.g. tuberculous meningitis and tuberculous spondylitis.

4. Administration of corticosteroids

In the first weeks of meningeal forms and in pericarditis.

5. Administration of pyridoxine

Isoniazid may cause peripheral neuropathy due to deficiency of this substance in certain situations. Prophylactic pyridoxine supplementation is recommended in patients with alcoholism, malnutrition, pregnancy, diabetes, renal insufficiency and HIV co-infection.

6. Treatment in HIV-infected patients

Rifampicin is a potent inducer of cytochrome P450 and accelerates the metabolism of many antiretroviral drugs, and lowers their plasma levels. Of the antiviral drugs, efavirenz is the drug of choice for treating HIV-infected patients who must also receive rifampicin.

Treatment of tuberculosis infection

Screening for possible infection should be done with a view to the possibility of initiating treatment in cases where it has been best demonstrated to be effective. (REF 7 T), such as in recent infection, HIV infection, recurrent lesions on chest X-ray and without previous treatment and in the case of patients who are to start treatment with anti-TNF- α .

The most studied treatment with proven efficacy is isoniazid. This efficacy would increase if given for 6 months or longer (up to 9 or 121 months). In co-infection with HIV, the usual recommendation is to extend it for 6–9 months if isoniazid is used. An alternative to isoniazid is rifampicin, especially when there is resistance to isoniazid, being used for 4 months. Finally, there is the possibility of using rifampicin and isoniazid for 3 months, with similar efficacy to the isoniazid regimen and better compliance (Ena and Valls, 2005; Spyridis et al., 2007).

In MDR-TB contacts, there is no recommended and proven effective scheme, so it is advisable to maintain surveillance with regular visits.

Treatment of infections caused by *Mycobacterium leprae*, *Mycobacterium ulcerans* and non-tuberculous mycobacteria

Mycobacterium leprae

The guidelines recommend a 3-drug regimen of rifampicin, dapsone and clofazimine for all patients with leprosy, with a treatment duration of 6 months for paucibacillary leprosy and 12 months for multibacillary leprosy. This represents a change from the current standard treatment for paucibacillary leprosy, which is rifampicin and dapsone for 6 months, due to some evidence indicating better clinical outcomes with a 3-drug, 6-month regimen over a 6-month regimen. For rifampicin-resistant leprosy, the guidelines recommend treatment with at least two second-line drugs (clarithromycin, minocycline), or quinolone plus two second-line drugs (clarithromycin, minocycline or quinolone) plus clofazimine per day for 6 months, followed by clofazimine per day for 6 months, followed by clofazimine plus one of these drugs for an additional 18 months. When ofloxacin resistance is also present, a fluoroquinolone should not be used. Fluoroquinolone should not be used as part of second-line treatment. The regimen of choice in such cases will consist of 6 months of clarithromycin, minocycline and clofazimine followed by clarithromycin, minocycline and clofazimine for an additional 18 months.

Mycobacterium ulcerans

It has been considered a disease of basically surgical treatment based on wide debridement and grafting. However, several studies suggest better results with early combination of drug treatment with a combination of rifampicin, clarithromycin and streptomycin (Nienhuis et al., 2010).

Mycobacterium avium complex

The introduction of macrolides (clarithromycin and azithromycin) has been a major breakthrough in the treatment of MAC infection. They have improved response rates compared to the classical regimens based on rifampicin, isoniazid and ethambutol in both pulmonary and disseminated HIV infection. Clinical response and in vitro resistance only correlates well with macrolides, where an MIC of 32 is clearly associated with treatment failure.

In MAC disseminated infection, treatment should be maintained for a minimum of 12 months, and may be suspended in patients with effective antiretroviral treatment who achieve virological suppression and CD4 counts above 100 cells for more than 3–6 months. The treatment of choice is the combination of clarithromycin and ethambutol.

In the case of pulmonary MAC infection, a combination of macrolide, ethambutol and rifampicin should be included. Differentiating between fibrocavitary (with the addition of an aminoglycoside) and nodular bronchiectasis forms is necessary for treatment. The duration should be 18–24 months and a minimum of 12 months from culture negative. Cervical lymphadenitis in children due to MAC can resolve spontaneously or produce spontaneous fistulas. The best results are obtained with surgical excision of the affected ganglia, although it is not clear whether it is necessary to add pharmacological treatment.

Mycobacterium Kansasii

The rifampicin, isoniazid and ethambutol regimen can be used for a minimum of 12 months from culture negative. In the initial phase or until sensitivity is known, a fourth drug (streptomycin, clarithromycin or quinolones) may be added. The in vitro activity of isoniazid against *M. kansasii* is lower than against *M. tuberculosis*. Despite this, treatments are effective, with rifampicin resistance accounting for the majority of therapeutic failures.

Mycobacterium xenopi

Sensitivity studies are difficult to interpret because of its slow growth, although it is usually considered sensitive to rifampicin, ethambutol, clarithromycin and high concentrations of isoniazid. It is recommended to treat with combinations of these drugs for 18–24 months, and a minimum of 12 months from negative culture in pulmonary disease (Philly and Griffith, 2015).

Mycobacterium malmoense

It is treated on schemes similar to those used against MAC, and is considered sensitive to rifampicin, ethambutol and clarithromycin, despite difficulties in the interpretation of in vitro sensitivity studies (Hoefsloot et al., 2008).

Mycobacterium szulgai

It is usually sensitive to rifampicin, isoniazid, ethambutol, quinolones and macrolides. Treatment with at least three active drugs for a minimum of 12 months from negative culture in lung disease is recommended (Tortoli et al., 1998).

Mycobacterium marinum

Systematic sensitivity studies are not recommended, as surgical excision of the lesion is often curative. It is usually sensitive to rifampicin or ethambutol, as well as tetracycline, cotrimoxazole or clarithromycin. Empirical treatment with ethambutol associated with clarithromycin and sometimes rifampicin is usually considered for at least 2 months after clinical cure (Aubry et al., 2000).

Rapidly growing mycobacteria

A special feature of fast-growing mycobacteria is their antimicrobial sensitivity, which is very different from that of slow-growing strains. In general, most fast-growing strains are resistant to the usual anti-tuberculosis drugs (isoniazid, rifampicin, ethambutol, pyrazinamide, and streptomycin), but are usually sensitive to other antibiotics used in the treatment of various bacterial infections, such as macrolides, linezolid, quinolones, imipenem or tigecycline.
